Tag der Promotion: 13.05.2016
Preface

The results presented in this thesis are the outcome of my work as a research assistant at the Institute of Databases and Information Systems of Ulm University between 2012-2015 with Prof. Dr. Manfred Reichert, as well as at the Computer Science Department of Aalen University of Applied Sciences between 2009-2012 working with Prof. Roy Oberhauser on the Q-ADVICE project (Quality ADVisory Infrastructure for Collaborative Engineering), where we created the Context-aware Software Engineering Environment Event-driven frameworK (CoSEEEK).

I am very grateful to my mentor Prof. Dr. Manfred Reichert, who I thank for his helpful advice, continuous support, and valuable feedback during the last years. He provided all the freedom needed for my research, but at the same time was always there to support me.

In addition, I am deeply grateful to my mentor Prof. Roy Oberhauser. This thesis would not have been possible without his initiative and extensive help and support, and I thank him for being a part of it. I could go to him with any problem or worry. He was a motivation and inspiration to me: not only his passion for science, but also his passion to really improve the situation for practitioners in software engineering, as well as his creativity and innovative ideas.

Besides my mentors, I would like to thank my second proofreader Prof. Dr. Franz Schweiggert and the members of my doctoral committee Prof. Dr. Peter Dadam, Prof. Dr. Helmuth Partsch, and Prof. Dr. Uwe Schöning for providing feedback for my thesis.

My thanks extend to my colleagues and students from the Q-ADVICE project for their support and help with the implementation of our concepts: Stefan Lorenz, Andreas Kleiner, Muhammer Tüfekci, Andreas Nägeli, and Alexander Grünwald.

I would also like to thank my colleagues and friends from Ulm University. It was a great time at DBIS, sharing so many different tasks with you.

Personally, I also want to thank Susanne for her help and continuous support in every situation. Her care and support during most of my thesis time made this the best time of my life, despite my spending so much time and attention on this project. She stood by me, and I am really looking forward to our future together.

Last but not least, I would like to thank my parents Heiderose and Peter Grambow. They were always there for me during the past decades, and always supported me with good advice in every situation. They enabled my studies in Aalen, Karlsruhe, and Ulm. For all of these things, and many more, I am deeply thankful.
Abstract

Historically, software development projects are challenged with problems concerning budgets, deadlines and the quality of the produced software. Such problems have various causes like the high number of unplanned activities and the operational dynamics present in this domain. Most activities are knowledge-intensive and require collaboration of various actors. Additionally, the produced software is intangible and therefore difficult to measure. Thus, software producers are often insufficiently aware of the state of their source code, while suitable software quality measures are often applied too late in the project lifecycle, if at all.

Software development processes are used by the majority of software companies to ensure the quality and reproducibility of their development endeavors. Typically, these processes are abstractly defined utilizing process models. However, they still need to be interpreted by individuals and be manually executed, resulting in governance and compliance issues. The environment is sufficiently dynamic that unforeseen situations can occur due to various events, leading to potential aberrations and process governance issues. Furthermore, as process models are implemented manually without automation support, they impose additional work for the executing humans. Their advantages often remain hidden as aligning the planned process with reality is cumbersome.

In response to these problems, this thesis contributes the Context-aware Process Management (CPM) framework. The latter enables holistic and automated support for software engineering projects and their processes. In particular, it provides concepts for extending process management technology to support software engineering process models in their entirety. Furthermore, CPM contributes an approach to integrate the enactment of the process models better with the real-world process by introducing a set of contextual extensions. Various events occurring in the course of the projects can be utilized to improve process support and activities outside the realm of the process models can be covered. That way, the continuously growing divide between the plan and reality that often occurs in software engineering projects can be avoided. Finally, the CPM framework comprises facilities to better connect the software engineering process with other important aspects and areas of software engineering projects. This includes automated process-oriented support for software quality management or software engineering knowledge management. The CPM framework has been validated by a prototypical implementation, various sophisticated scenarios, and its practical application at two software companies.

Part I

Problem Statement and Requirements
1. Introduction

Software Engineering (SE) is a discipline that implies special properties for process enactment. On one hand, these are correlated with the special properties of the produced product, i.e., the software: complexity, conformity, changeability, and invisibility [Broo87]. On the other, IT support for SE processes is not mature yet, since SE implies a highly dynamic and creative process. Furthermore, the impact of process management in SE has been underestimated for a long time [Wall07]. Over decades, many SE process models as well as models for SE process improvement have been developed and been introduced to practice. In other areas, like industrial production, such processes have been automated and supported by process management technology [LeRo00]. Yet implementation and automated enactment of processes is not prevalent in SE, mostly due to the dynamic nature of these knowledge-intensive processes that contradict the rigid sequencing of process activities necessary for an automated enactment.

SE processes are essentially knowledge-intensive, i.e., they depend on knowledge workers to a large extend [KeHa02]. The highly intellectual SE process implies a high amount of communication. Compared to industrial production processes, SE processes rely much more on humans and highly collaborative team interactions. Note that each SE project constitutes a development project, producing a unique outcome. For such projects, the rigidity of prescribed processes mostly does not fit. Further, it was already stated that dynamic processes supporting collaboration as well as communication can be beneficial [Shet97]. Usually, SE processes deal with the development of a new product (i.e., the software), which is a knowledge-intensive task [RaTi99]. In this context, necessary facts, much information and comprehensive knowledge are handled manually and implicitly by the humans involved. Hence, automation is not feasible and SE processes are usually performed manually in a documentation-centric way [RBTK05]. In turn, this often implies high manual efforts for humans as they have to manage the process models. Moreover, actual process enactment largely depends on humans. Many tasks and activities are not part of the process models. Especially on the operational level, where activities like coding and testing are performed, only limited support for the software engineers is available from SE process models. Thus, there is a growing gap between the specified process and the one actually executed.

Another specialty of SE projects is the product developed. Software has special properties whose combination differentiates it from many other products: complexity, conformity, changeability, and invisibility [Broo87]. These properties make it difficult to be aware of the status of the software. In many software producing companies, human tasks, requirements, and the realization of the requirements are managed in some way. However, due to the often high number of humans working concurrently on numerous source code artifacts, the quality of the source code can deteriorate unnoticed. Thus, many projects struggle with bad source code quality [Jone10]. However, to be enforced, software quality must be defined and measured [Kan02]. In many cases, resources are wasted by neglecting software quality issues and respective software quality measures until the final stages of a project [Hami88, SHK98]. Another issue of software quality comes with the lacking ability of many companies to actually control, manage and support their knowledge-intensive and human-centric processes [BDS+99, Amblo2, Wall07, Dust04, SBBK08]. Due to these issues, projects suffer from bad software quality as well as exceeded budgets and deadlines having issues on both the process and the product side. Altogether, it is desirable to integrate software quality assurance tightly and smoothly with process management to enable the continuous monitoring of product quality.

Business Process Management and the introduction of Process-Aware Information Systems (PAIS) has been a continuous trend in various business areas. In particular, the explicit governance of activities by a PAIS enables improved repeatability of the process and can thus improve the quality of the product [ReWe12, DAH05]. Domains in which PAIS have been successfully introduced include
health care [LeRe07], automotive engineering [MHHR06, MRH08], finance [GoAk03] and transportation [Bass05]. To be able to comprehensively cover all activities executed as well as optimize the whole process executed in an organization, the business process lifecycle [GeTs98, vdAa04, WRWR09] is roughly separated into several phases (cf. Figure 1-1): First the process is defined, which implies a design process. Further, this phase might include the discovery of executed processes through process mining [vdAa11, vdWe04, vWM04]. Following the design phase, the process is implemented. In the subsequent enactment phase, the process is used to govern the activities it was designed for. Data from this enactment phase is then used for the diagnosis phase, which can be applied to optimize the process as well as to adapt it to environmental changes. With the results from the diagnosis phase the cycle can be restarted.

To enable continuous support and guidance for a process, automated IT support is desirable. To achieve the latter, processes can be implemented using PAIS [vdvH02]. Such systems provide support for automated process enactment, automated task distribution to humans, coordination, and monitoring of different process instances. That way, process enactment can be guided and process diagnosis be supported, since the executed activities are explicitly governed. This makes the entire process enactment more traceable and repeatable.

The described factors hamper successful process enactment in the SE domain. Many of the issues discussed, however, are related to the dynamics of SE projects [BDS+99, Ambi02]. In fact, numerous obstacles inhibit automated SE process management (SEPM) at the operational level. These include a high number of dynamically executed small tasks like bug fixing, coding, developer tests, or integration tests. Respective tasks may not even be covered on the more abstract planning levels where the entire project, its process, and different phases are managed. Such activities also imply many contextual dependencies, i.e., they rely on properties relating to the current situation, e.g., time pressure in the projects or technology used. Another factor is the great number of involved artifacts, e.g., documentation artifacts, specifications, or the source code itself. These artifacts often have many relations with each other and are frequently changed by various persons. This involves a great amount of tacit knowledge crucial to the projects that is only implicitly managed by these persons. In turn, this puts high pressure on them: Because of the high dynamicty, the concurrent enactment of multiple projects, the absence of clearly defined and stable requirements, and many other factors, much is left to them. This constitutes a great burden as well as high efforts for software engineers. Due to the lack of repeatability and guidance of these knowledge processes, it is rather likely that the knowledge worker forgets important tasks or unintentionally introduces new problems to the source code.
1.1. Problem Statement

As shown by many studies, SE projects have been suffering from problems with exceeded budgets, missed schedules, and low product quality for a long time [NaRa68, Broo87, Glas98, Kruc04, Jone10]. Many of these problems are resulting from the adolescence of SE as a discipline and special properties of this discipline having a great impact on SE projects. These properties (e.g., the intangible product or the knowledge-intensive, human-centric SE process) are exhibited, in both the created product and in the SE process. Based on this, three main topics introducing serious issues to SE can be observed: First, the knowledge-intensive process puts much pressure on the involved humans. Second, the intangible product makes it difficult to control the latter and might introduce severe quality issues. Looking at these two problematic sides of SE projects, a third topic comes into mind: there exist tools that support various SE aspects but no comprehensive and automatic process support, incorporating humans and artifacts, is prevalent.

Note that we will use the term process and workflow with different meanings. Process will be referred to as something rather abstract that is not implemented in software. Workflow will be referred to as something more concrete and operational as well as something that is implemented using a software tool and, therefore, as an automated facility to govern the flow of activities.

Manual process implementation. Process automation was mainly applied in areas in which foreknown activity sequences exist, but not in scenarios requiring the enactment of a human-centric and knowledge-intensive process [MBR15]. In SE, therefore, there exists not much experience with process automation. Process models are available containing information important for the projects [BWHW06, RiJa00, Mall09]. However, these remain rather abstract and prescriptive [BDS+99, Ambl02]. Hence, manual implementation becomes necessary. Consequently, the involved persons are responsible for enacting the SE process without automated governance or enforcement. This implies shortcomings with respect to guidance, traceability, monitoring, and diagnosis of the activities executed, as abstract process models mostly do not reach the actual executing persons [Wall07]. In particular, they tend to fail in providing operational guidance. Since the quality of the software product is depending on the quality of the SE process [Wall07], this affects product quality as well. The gap between the abstract process models and the actual executed activities also prevents comprehensive coverage of all activities in the SE process. Many activities are executed ad-hoc and cannot be traced. However, if many are activities executed outside the SE process, knowledge about actual process enactment cannot be established. In turn, this makes it difficult to enable reproducibility of processes and projects or the process improvement measures applied.

Knowledge-intensive processes. The issue with lacking process automation is epitomized by the fact that the process is both complex and knowledge-intensive. As stated, SE processes involve new product development, which is a knowledge-intensive task [RaTi99]. Even if not dealing with product development, SE processes are mostly knowledge-intensive [KeHa02]. There is a need for capturing and sharing various types of information, including domain knowledge, knowledge about technologies, or knowledge about national or local policies [LiRu02]. Supporting this with an automated tool can be beneficial [TFB00]. Often, Wikis are used for SE knowledge management since they can be easily created and information can be quickly accessed [SBBK08]. However, retrieving contextually relevant information from Wikis is a difficult task [SBBK08]. Thus, knowledge management as well as knowledge transfer is hampered. However, SE is essentially a collaborative activity [JYW07, CoCh06]. Consequently, the other side of knowledge-intensive processes concerns the collaborations of the various individuals working in these processes [MBR15, MuRe14]. The different connections between humans, teams, tools, and artifacts are of crucial importance for SE success [JYW07, SQTR07]. However, efficient communication and process-aware collaboration remain a great challenge [Dust04], and, to a large extend, team work remains unpredictable and unplannable [BSV07]. Moreover, collaborative work in SE is still not adequately supported by tooling in SE [LeBo07].
**Product quality issues.** The created product – the software – has specific properties making it difficult to monitor and control its status. In turn, this complicates SE projects. Software Quality Assurance (SQA) has proven to be essential for SE. In particular, it has been shown that SQA has impact on project costs [Hami88, KKKM00, HuBo06, MSG13], which makes effective and efficient SQA mandatory. Effective application of software measurement remains a big challenge for software vendors [STT06]. Furthermore, software quality measures are often applied too late in the projects, although it has been proven that their application in earlier stages could save time and money [Hami88, SHK98]. Note that the application of quality measures is also problematic, since their effectiveness as well as efficiency depend on various factors, like the applicability of the measure, the project timing, worker competency, or correct execution of the measure [Hami88].

### 1.2. Contribution

This work originated from the Q-ADVICE (Quality ADVisory Infrastructure for Cooperative Engineering) project, whose goal of this project was the creation of a concept as well as a prototypical framework supporting the SE process. That concept as well as the framework shall enable the automation of various supportive aspects enhancing the quality of the SE process as well as its product. In Chapter 13, various aspects regarding the technical implementation of a prototype framework are discussed. All chapters before that deal with the abstract approach that extends process management technology to enable holistic support for SE projects taking into account the different aforementioned problem areas. We call this approach CPM (Context-aware Process Management). Its core contributions are aligned to the core problems identified:

- **SE process model implementation support:** CPM supports the implementation of entire SE process models. It provides facilities to enable automated process enactment in SE projects. This includes support for all process levels ranging from abstract processes to the concretely executed workflows. Further, CPM provides facilities to integrate process enactment directly with the project environment. Thus, a connection between the abstract process models and the concrete activities on the operational level is established. Context information is automatically collected and utilized for various purposes.

- **Advanced SE process enactment:** CPM also integrates advanced process enactment features to support dynamic domains as SE. It features dynamic processes, i.e., predefined processes may be dynamically adapted to match different situations. Furthermore, CPM enables context-sensitive adaptations, i.e., automatically collected context data is utilized to adapt running processes to the needs of the current situation. Further, CPM features facilities to model and execute dynamic workflows that are usually not covered by SE process models. Thus, these workflows can be integrated with standard process enactment, and, hence, can be guided, traced, and can profit from other CPM functionalities. Finally, CPM incorporates advanced facilities for exception handling. These take various types of context knowledge into account, as, for example, the states of activities, artifacts, or the SE process. Furthermore, CPM enables flexibility and automation for handling exceptions and is capable of not only automatically determining the right exception handling, but also the right person and time point for applying the handling.

- **Integration of processes with other areas of SE projects:** CPM integrates process enactment with other areas important for SE projects. One of these is quality assurance. This includes the automatic detection of potential problems in source code artifacts as well as the management of quality goals, proactive quality measures and reactive quality measures. Furthermore, quality measures can be prioritized according to quality goals and be automatically and context-sensitively distributed to the executing persons in alignment with their standard process activities. Another important area is SE knowledge management. CPM enables automatic management of collected SE knowledge utilizing machine-readable semantics. That way, the context-sensitive selection of applicable knowledge for SE engineers becomes possible. Furthermore, that knowledge can be automatically injected into the running process to support SE engineers in various situations. Finally, CPM supports collaboration in SE projects. It features various types of meta information that allow automatically recognizing coherences between different activities and artifacts even if they are executed in different areas or departments of a project and by different
persons. With this information, different types of automated coordination become possible ranging from simple information distribution to fully automated creation and distribution of new activities.

This work provides an evaluation of the developed concepts as well. By implementing a prototypical framework, questions regarding the technical feasibility of the approach are dealt with. Furthermore, detailed studies demonstrating the applicability of the approach were conducted and the framework was applied in two practical settings.

1.3. Outline

This thesis is split into five parts:

**Part I (Problem statement and requirements)** provides the motivation of holistic process and project support for SE. In Chapter 2 research question and research methodology are described. Chapter 3 provides background information on the SE domain and SE processes, whereas Chapter 4 elicits basic requirements for a tool providing automated holistic support in this domain.

**Part II (Solution)** is devoted to the solution. It starts with Chapter 5 providing basic information needed for understanding the work. In Chapter 6, the abstract solution approach is described. Then, Chapter 7 discusses the contextual extensions to process management concepts being the basis for all other components of the solution. Chapter 8 elaborates on the approach taken for modeling and enacting dynamic workflows extrinsic to the SE process models. In turn, Chapter 9 discusses automated contextual support for SE quality management. Chapter 10 gives insights into task coordination and Chapter 11 deals with SE process exception handling. Finally, Chapter 12 describes the automated contextual integration of knowledge management into the SE process.

**Part III (Evaluation)** is dedicated to the evaluation. Chapter 13 gives details on the technical feasibility and the implementation of the approach. Chapter 14 shows the practical applicability of the solution to a set of concrete scenarios. Finally, a discussion of related work and threats to validity is provided in Chapter 15.

**Part IV (Conclusion)** concludes the thesis with a summary and an outlook.
2. Research Methodology

This chapter presents the research questions addressed by this thesis as well as the research methodology applied.

2.1. Research Questions

Chapter 1 presented a problem statement and distilled main problem areas backed up by literature references: (1) the inadequate process support and implementation in SE; (2) the inadequate support of humans and their interaction in these knowledge-intensive processes; and (3) the inadequate integration of the product and its quality management into these processes. The first item corresponds to the process itself while the other two items refer to the integration of the process and other important aspects of the SE project. Thus, this thesis deals with three main research questions, the first being the general leading theme of the thesis and the other two refining the first.

Research Question 1: Is it possible to support SE projects by not only documenting, but operationally guiding and supporting their processes?

Research Question 2: Is it possible to operationalize and guide entire SE process models with (existing) automated tools?

Research Question 3: Is it possible to connect SE process enactment comprehensively to the actual course of the projects including artifacts and humans?

To answer these research questions the course of action is to analyze SE projects in practice as well as to do a comprehensive literature study. Based on this, we will create more concrete requirements to be fulfilled to answer the research questions.

2.2. Information Systems Research

In particular, this work deals with information systems supporting humans in SE. Therefore, this work relies on a combination of two science disciplines applied for Information Systems (IS) research that was postulated in [HMPR04, HeMa03]: design science and behavioral science [MaSm95]. In the following, we will briefly explain this combination and its suitability for this work.

Information Systems research approaches following behavioral science seek to provide a better understanding of the interplay of organizations, humans, and technologies that have a huge impact on the performance of those organizations. Behavioral approaches, therefore, develop theories to explain or predict organizational phenomena concerning the management, implementation, design, and analysis of IS. Opposed to this, design science aims to create and evaluate concrete artifacts solving the problems identified. These approaches are problem- and solution-oriented having their roots in engineering and sciences of the artificial [Simo96]. As opposed to natural science, however, design science approaches do not examine natural phenomena, but rather deal with those relating to and created by humans [Simo96].
Design plays a central role in these approaches and is to be understood as the goal-driven and deliberate organization of resources for achieving these goals. The combination of these two disciplines has been chosen in this thesis due to its applicability for complex and application-centric IS problems. The latter often cannot be precisely specified (i.e., as mathematical model) and thus cannot be optimally solved by one approach. Instead, they demand for more flexible descriptions and solutions. As an example, [Simo96] presents the creation of a robust IS architecture and classifies solutions to such problems as ‘satisfying’. This means that they may not be optimal, but well suited and good enough for a certain class of problems.

In this work, the framework created in [HMPR04, HeMa03] is applied as shown in Figure 2-1:

As the first step, concrete experiences and information were gathered from two software-producing small- or medium-sized enterprises (SMEs). On one hand, this information comprises concrete requirements and the research goals. On the other, it consists of information about the concrete infrastructure of these organizations, including artifacts, humans and tools.

In the second step, a detailed literature study was conducted revealing information crucial for the SE domain. This included information from various applications for purposes like knowledge management or process management as well as SE domain knowledge (i.e., process models or best practices).

Based on the information gathered and aggregated, a framework was designed and developed. To ensure practical applicability, the evaluation not only included different case studies but also a concrete application of the developed framework in two practical settings.

For combining design science and behavioral science in IS research, [HMPR04, HeMa03] postulated seven guidelines that shall ensure the validity and effectiveness of that research (cf. Table 2-1). In the following, the application of these seven guidelines to this work is briefly discussed. Guidelines 1 and 7 are strictly followed as all efforts of this work result in concepts, algorithms and methods published in scientific papers. The relevance of the objectives was proven by sources from literature as well as the information gathered from two industrial software companies. The evaluation recommended by Guideline 3 is conducted through practical usage by two software companies. As such industrial evaluation with only three small teams is relatively fuzzy and error-prone, a set of concrete case studies has been created to evaluate the applicability of the different contributions of this thesis. Further, this work has a set of concrete contributions (cf. Guideline 4) outlined in Section 1.2. The research rigor (cf. Guideline 5) is facilitated by not only creating design artifacts, but also using these artifacts to create a concrete applicable solution (software) that can be practically applied. The search
process recommended in Guideline 6 was also followed. By the usage of concrete scenarios and a practical application, solutions that may not be optimal but yet satisfying for the problem were found.

Table 2-1: Research guidelines (adopted from [HMPR04])

<table>
<thead>
<tr>
<th>Guideline</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>G1: Design as an Artifact</td>
<td>Design-science research must produce a viable artifact in the form of a construct, model, method, or instantiation.</td>
</tr>
<tr>
<td>G2: Problem Relevance</td>
<td>The objective of design-science research is to develop technology-based solutions to important and relevant business problems.</td>
</tr>
<tr>
<td>G3: Design Evaluation</td>
<td>The utility, quality, and efficacy of a design artifact must be rigorously demonstrated via well-executed evaluation methods.</td>
</tr>
<tr>
<td>G4: Research Contributions</td>
<td>Effective design-science research must provide clear and verifiable contributions in the areas of the design artifact, foundations, and/or methodologies.</td>
</tr>
<tr>
<td>G5: Research Rigor</td>
<td>Design-science research relies upon the application of rigorous methods in both the construction and evaluation of the design artifact.</td>
</tr>
<tr>
<td>G6: Design as a Search Process</td>
<td>The search for an effective artifact requires utilizing available means to reach desired ends, while satisfying laws in the problem environment.</td>
</tr>
<tr>
<td>G7: Communication of Research</td>
<td>Design-science research must be presented effectively both to technology-oriented as well as management-oriented audiences.</td>
</tr>
</tbody>
</table>
3. Background

This chapter provides background information on the characteristics of the SE process and SE process models, respectively. Section 3.1 briefly discusses basic properties of SE process enactment. Section 3.2 then introduces prevalent SE process models as suggested in literature. We provide historical background and then present models prevalent in contemporary SE projects.

3.1. The Software Engineering Process

[BrBe11] provides the following definition of a software process: "A software process is a framework for carrying out the activities of a project in an organized and disciplined manner. It imposes structure and helps to guide the many humans and activities in a coherent manner. A software project progresses through different phases, each interrelated and bounded by time. A software process expresses the interrelationship among the phases by defining their order and frequency, as well as defining the deliverable of the project. ... Specific software processes are called software process models."

As already stated, the SE process is highly dynamic. On one hand, this results from the properties of the created product (i.e., the software). On the other, the creation of the product implies a highly intellectual, creative process that, in turn, necessitates much communication. The latter is needed across different abstraction levels (i.e., from the high level process of a project down to the operational level where concrete activities are executed) as well as different project areas (e.g., 'Quality Management' or 'Software Implementation'). This section enumerates the various groups of persons involved, tasks executed, and artifacts processed in order to explain communication channels as well as the highly dynamic properties of an SE process.

Usually, SE involves various roles [BrBe11]. First of all, there are the software vendor and its customer, who have to agree on the product to be delivered. As part of the software vendor, there exist vertically and horizontally divided areas. Vertically, there are levels such as company and business management, project management, and project staff. Horizontally, aligned from the first product idea to the final product, different teams participate: the requirements analysts communicate with the customer eliciting concrete requirements for the product to be developed. They represent the customer towards the developers. The architects are responsible for the technical foundations as well as architecture of the software and design decisions. In turn, the developers are in charge of the concrete realization of the requirements based on the chosen architecture. A test team verifies the technical functionality of the software, while the requirements analysts are in charge of the functional inspection of the software. Other responsibilities are related to configuration management, problem and change management, and administration. Furthermore, it is common that multiple companies collaborate to create one product or that in one company many projects are executed concurrently. Figure 3-1 shows a schematic description of a selection of different actors, artifacts, activities, and areas of an SE project together with their relations.
Besides the source code, the artifacts processed in a SE project include various plans and specifications. In the following, a selection of artifacts are presented that have been standardized by the Institute of Electrical and Electronics Engineers (IEEE). The software requirements specification (SRS) [IEEE98a] covers the requirements of the software to be developed. The requirements can be split into two parts: customer requirements (similar to the German 'Pflichtenheft') and development requirements (similar to the German 'Lastenheft'). A software quality assurance plan (SQAP) [IEEE02] covers all development, testing and training activities in the project. The software configuration management plan (SCMP) [IEEE05], in turn, describes the necessary configuration management activities. The software test documentation (STD) [IEEE07] contains the documents needed for documenting the software tests. The software validation and verification plan (SVVP) [IEEE04] manages how the validation and verification of the software shall be documented. The design of the software is captured in the software design description (SDD) [IEEE09] and the governance of the entire project is described in a software project management plan (SPMP) [IEEE98b].

Usually, SE projects aim to create or extend software. In this context, various tasks need to be accomplished and coordinated among different groups of persons implying different artifacts. A project begins with the elicitation of its requirements. After their definition, the system architecture must be chosen and built. In parallel, the solution concept needs to be developed, which is mostly done in more than one step producing a preliminary concept first. The actual realization phase starts after having determined all parameters. To be finally deployed the solution must first be tested and, eventually, its different parts be integrated. The entire SE process is rather dynamic due to different factors: The intangibility of the created product makes it difficult to preplan it comprehensively implying a thing called ‘requirements creep’ [Jone96]. The latter describes the fact that in most SE projects requirements are evolving and cannot be concretely defined upfront. Another negative effect of the software’s properties is its aggravated measurability according to quality. To be able to improve
the latter, quality goals must be defined and measured [Kan02]. However, many companies are suffering severe problems in implementing effective measurement programs [STT06].

3.2. Software Engineering Process Models

Explicit SE process models have been developed and used for a long time in SE in order to enable governance, guidance and support for the SE process. In addition, such SE process models shall improve quality of the SE process as well as the produced product by enhancing repeatability and avoiding uncoordinated ad-hoc activities. Furthermore, process models can be the basis for process improvement since a process must be known to improve it. The following sub-sections give a brief overview about common SE process models and approaches.

3.2.1. Classical Approaches

Classical approaches in process specification have existed for many decades. Compared to the more recent agile approaches, they are based on a rather static and heavyweight process model.

Waterfall Model

The waterfall model [Royc70], which can be seen as the earliest structured system development approach, was mentioned first in 1970. It describes a sequential SE process, which originates from the manufacturing industries, and includes the phases depicted in Figure 3-2.

![Figure 3-2: The waterfall model](image)

These phases are processed sequentially, assuming that a phase transition is only executed if the current phase is finished. The process allows going back one step to the preceding phase, but not further. The waterfall model has turned out to only poorly capture the properties of the SE process. In particular, in SE it is usual that the requirements cannot be completely elicited before development starts. As another disadvantage in SE, designs often cannot be translated into working products in a straightforward way due to various limitations like, e.g., regarding technology.

Spiral Model

The spiral model combines elements of prototype-driven process methods with the classical SE process of the waterfall model [Boeh88]. The former takes into account that it may be difficult to know all system requirements upfront and thus proposes the development of system prototypes first. Its primary focus is to manage and reduce the risks of the overall SE process. Figure 3-3 shows the different phases of the process model.
The process of the spiral model is represented as an expanding spiral corresponding to iterative developments. The inner cycles represent early development stages with system analysis and prototyping. In turn, the outer cycles represent the classic development cycle. Each cycle begins with the activity of risk analysis to incrementally identify critical factors in the project. The model is intended for big projects in risky areas and may imply too much management overhead for smaller projects.

**V-Model**

The V-Model is named after the alignment of its activities in the process model: activities are aligned like a ‘V’ as illustrated in Figure 3-4. The left side represents the elicitation of requirements and the creation of various specifications, whereas the right side represents the verification and integration of the developed system parts. The main objectives are the improvement of product quality and the minimization of risks as well as the facilitated communication of stakeholders and cost reduction for the whole project. The V-Model was initially developed for the German Federal Ministry of Defense in 1986. It was refined later to the V-Model 97 incorporating new approaches like object orientation. In 2005, it re-experienced a major refinement to the V-Model XT (eXtreme Tailoring) [IABG15]. The focus of the new model was to be easily tailorable to various organizations. It further considered stronger involvement of the customer, stronger modularization, and orientation towards incremental approaches. As opposed to the models described before, the V-Model XT is a rather heavyweight model, not only roughly describing different development phases, but also comprehensively covering different project roles and groups as well as their communication (i.e., describing ‘Who’ has to do ‘What’ and ‘When’).
As shown in Figure 3-4, the V-Model not only comprises development tasks, but project acquisition and definition tasks as well. For concrete development tasks (starting with ‘System specified’ until ‘Shipment conducted’), multiple iterations may be applied. The activities to reach the milestones are rather abstract and comprise a number of more fine grained sub-activities. To group the latter, so-called process modules are used. For example, process module ‘System Development’ comprises 49 activities (e.g., ‘Preparing overall system specification’) of which some are even specified as a workflow. Furthermore, the mentioned process module comprises 73 so-called products (i.e. artifacts) like ‘In-service documentation’ (includes all data needed by the customer to properly operate the system). These products have relations to the various activities as well as to roles (e.g., ‘Requirements Analyst’). Furthermore, they have complex mutual relations, which include the ‘Content-Related Product Dependencies’ describing content-wise relations in the products, and ‘Generative Product Dependencies’ describing that one product is needed creating another. A key feature of the V-Model XT (eXtreme Tailoring) is its capability to tailor it to the current project by adding or omitting certain process modules even while the project is active.

### 3.2.2. Agile Approaches

Agile SE approaches [FoHi01] have emerged since classical approaches often fail to cover the dynamic nature of the SE process. In particular, agile approaches put more emphasis on the humans enacting the process as on the process itself. Responding to change is more favored than rigidly implementing a process model. Consequently, small, self-organizing teams are installed. Furthermore, the customer is more tightly integrated into the SE process in order to be able to quickly communicate changing requirements. Another important aspect concerns the utilization of short cycles, which should always produce a working product. Thus, the customer can already get familiar with the product and requirements changes can be communicated earlier.

**Scrum**

Scrum [DeSt90, TaNo86, ScBe01] is rather a framework than a full process model. Thereby, many of the decisions in the SE process are left up to the team. Scrum teams are self-organizing and cross-functional, meaning they comprise members of different groups such as developers, requirements analysts, or testers. The Scrum process defines three main roles: ‘Scrum Master’, ‘Product Owner’, and ‘Scrum Team’. The ‘Scrum Master’ is a kind of team leader whose main responsibility is the support of the ‘Scrum Team’ by removing impediments that prevent the team from completing its tasks. In turn, the ‘Product Owner’ is something like a proxy for the customer of the project: He analyzes business needs and defines the requirements for the ‘Scrum Team’. The latter is in charge of realizing the functionalities of the software to be produced. Figure 3-5 illustrates the process model.
As shown in Figure 3-5, the Scrum process features different artifacts called ‘Work Products’. These can be separated into two categories: ‘Task Board’ and ‘Burndown Charts’ that list different activities to be accomplished within a certain timeframe. The requirements (i.e., different functionalities of the software) are represented by the ‘Product Backlog’, ‘Sprint Backlog’ and ‘Potentially Shippable Product’. At the beginning of a project, which starts with the ‘Release Planning’ activity, the ‘Product Backlog’ (including all desired functionalities) is specified and the number and length of sprints is determined. After that, the backlog items are estimated by the team and prioritized by the ‘Product Owner’. In the ‘Sprint Planning Meeting’, it is determined which items shall be realized in the current sprint. These items are then moved to the ‘Sprint Backlog’. Within a sprint, all scheduled backlog items are realized and everyday a short ‘Daily Scrum’ meeting is conducted for coordination purposes. At the end of a sprint, the backlog items are reviewed with a presentation of the ‘Potentially Shippable Product’ in the ‘Sprint Review Meeting’. Following the latter, there is an additional ‘Sprint Retrospective Meeting’ to discuss the past sprint.

**eXtreme Programming**

eXtreme programming [Beck00a, Beck00b] targets at smaller teams and the programming tasks constitute the main focus. As fundamental assumption, the customer does not know all requirements prior to project start. Therefore, the entire process is organized incrementally and dynamically. Requirements are described in terms of user stories which are a lean form of use cases focusing on the user’s view of the system. Extreme programming describes an open, fluent process that relies heavily on the participation of humans.

Some key practices are mentioned in the following: Programming is mostly done as pair programming where two developers share one computer to develop the software. That way, knowledge transfer shall be furthered and the error detection rate shall become high. Tasks are not distributed to humans, but to the team, and then become dynamically distributed. Humans do not have strict responsibilities and work is always shared. The dynamic process builds on permanent testing, integration and refactoring of the code.
Criticisms of extreme programming target at the low level of governance it provides, while relying heavily on the participation of the involved humans, which presumes ideal developers and customers. The process can be seen as too dynamic because it assumes continuous change. It has been proven that changes of the requirements get more expensive in later project stages. Furthermore, in extreme programming, it can be difficult to guarantee an exact amount of functionality at an exact time point.

**Unified Process**

The unified process [JBR99, Scot02] is an iterative SE process framework that is very popular and has many derivates. As its two main characteristics, this process strongly focuses on the architecture of the developed software and on addressing the risks in early project stages. The unified process knows four project phases as depicted in Figure 3-6.

Figure 3-6: The Unified Process (OpenUP, adopted from [EcFo15])

The four phases (Inception, Elaboration, Construction and Transition) are separated into iterations. In each phase, different amounts of work in the core disciplines are accomplished. These disciplines are business modeling, requirements analysis, system analysis & design, implementation, testing, deployment, configuration & change management, project management, and environmental tasks.

The unified process comprises several refinements with different focus. Probably, the most well-known is the rational unified process (RUP) [Kruc99]. RUP is a sophisticated and heavyweight variant, which governs activities in great detail. RUP contains over 30 roles and over 130 activities. Thus, it can be used effectively only in teams of more than ten humans. Another refinement is the Open Unified Process (OpenUP) [Ecfo15], which is part of the Eclipse process framework (EPF). All these RUP variants aim to provide a simpler, open version of the process, while capturing all essential characteristics of the unified process or RUP. OpenUP features three levels of granularity: At the project level there are four phases (as defined by the Unified Process): Inception (roughly agree upon the goals of the project), Elaboration (agree on the technical approach), Construction (realize main part of the system), and Transition (make the system ready for its transition to customer). Within each of
these phases, multiple iterations may take place. The iterations, in turn, comprise several more fine-grained activities (e.g., ‘Develop Solution Increment’ for developing a new part of the software). These activities may be specified in terms of workflows containing even more fine-grained activities (like ‘Implement Solution’ or ‘Implement Developer Test’). The OpenUP process features different kinds of guidance to support the project participants. Activities on the most concrete level are supported by so called steps that roughly outline what has to be done to complete the activity. Furthermore, the model features concrete checklists to be applicable at certain points.

3.3. Summary

This section provides a summary about the SE process extracted from the properties and criticisms of the introduced process models. Due to the numerous efforts regarding explicit process models, it is evident that they are essential for SE projects enhancing repeatability, traceability and, first of all, quality of the process and thus of the product as well. Yet, it cannot be guaranteed that process models are followed since they are mostly abstract and applied manually and documentation-centric.

The waterfall model and in the particular the criticism on it show that a rigid process is not the right choice for mirroring the dynamic properties of the SE process. This results to a great extend from the fact that all requirements can be known a priori only in very rare cases. The Spiral model, in turn, tackles this issue as it provides an iterative process, which strongly targets at risk analysis and prevention. Criticism on that model include that it is too heavyweight and not applicable to all kinds of organizations. Finally, the V-Model XT incorporates far-reaching tailoring facilities to be applicable to different organizations. It also puts a strong focus on risk management and communication support. Yet it is still rather heavyweight and thus not suitable for small projects or teams.

Agile approaches were developed as answer to the heavyweight classical process models. Scrum, in turn, puts a strong focus on humans and small self-organizing teams. eXtreme Programming is even more targeted towards the individual. These approaches are lean, but criticism includes that there is not enough governance and thus unpredictable results might be produced. The Unified Process is more static focusing on the architecture. However, some refinements, including RUP, are considered too heavyweight, same as the classical approaches.

All in all, comparing the criticism of the classical and the agile approaches, one can state that it is difficult to provide appropriate process support for SE projects. On one hand, comprehensive process models are often too static and require much cumbersome additional work imposed by the process model. On the other, leaner and more dynamic process models often lack comprehensive support. In particular, they considered to be chaotic and heavily relying on humans. Another fact we discussed constitutes the diversity in SE process models. It is therefore not easy to select process support matching the current company, organization and situation. None of the mentioned process models seems to be applicable to all types of organizations. Altogether, it can be stated that striking a balance can be beneficial, i.e., to provide process guidance without implying too much distractive additional work. A tool providing automated assistance may aid in reaching that goal, taking cumbersome tasks in heavyweight process models and supporting agile teams in the background.
4. Requirement Analysis

This chapter deals with concrete problems and elicits basic requirements from the abstract problems discussed in Chapter 1.

4.1. Concrete Problems

Basically, this work aims to support humans and to address the abstract problems discussed in the preceding sections by a framework. In SE, various tools are prevalent supporting different aspects of process implementation, knowledge management, or quality management. However, many problems remain unsolved as mentioned by the various studies we reference in the relating chapters. To better understand these problems and to support requirements elicitation, we split the three abstract problems up to derive a greater set of more concrete problems that can be better connected to SE tool support.

As summary of these problem statements, we extract eight concrete problems relating to SE projects and their process having a big impact on the quality of both the SE projects and the products created by them (cf. Figure 4-1). The latter is separated vertically: On the left side, process specification utilizing abstract process models is depicted. In the middle, the (automatically supported) implementation of such process models is shown for concrete projects. Finally, the left side depicts the SE process as it is really executed by humans creating and manipulating artifacts using SE tools.

We will further support these problem statements by concrete scenarios. The latter were created with information from literature and especially with information gathered from two practical settings. For confidentiality reasons the scenarios are abstracted and generalized. Further, they are centered around a fictional company called ‘The Company’. Not all of the scenarios directly correlate with an abstract problem identified in the Problem Statement. In particular, the first three problems (Automated Process Governance, Context Integration, and Process Dynamicity) are of abstract nature playing a role in most of the scenarios.

Lack of Automated Process Governance (Prob:AutoProc). One problem area concerns process tracking and guidance, referred to as automated process governance in the following. If a project is to be executed in an effective, efficient and repeatable manner, studies have shown that it should be based on a defined process [GGK06]. Furthermore, process models may contain important information about the projects [BWHW06, RiJa00, Mall09]. As discussed in Chapter 3, many SE process models have been developed including Scrum [ScBe01], the Unified Process [JBR99], or the V-Model XT [IABG15, RBTK05]. As a problem, typically, these models exist only on paper or web pages, i.e., they are only used for process specification and documentation. In many cases, the process is rigid and prescriptive, and it differs from the real dynamic work performed in a project [BDS+99, Amb02]. Furthermore, the impact of the models on actors and concrete activities often remains low [Wall07]. Automated support for enacting such process models is desirable. There are numerous tools capable of automated workflow governance. These tools strongly focus on the control-flow perspective meaning they are capable of governing the sequencing of different activities and transferring different tasks to the humans. In addition, they often provide limited means for integrating data objects and an organizational model. However, they fail in covering the different aspects of process models like guidelines or checklists, or dynamic features like the V-Model XT’s dynamic tailoring (cf. Chapter 2). Consequently, the automatically assisted implementation of a whole process model with such tools remains a challenge.
Lack of Context Integration (Prob:ContInt). A second important problem area concerns contextual integration: even if some automated process implementation and guidance is present in a project, this does not necessarily mean that the specified and actually executed processes align. In reality, a myriad of environmental variables affect process enactment [Schw97, MaVe03, BPNS07]. In SE, the latter mostly deal with various actors using different tools (e.g., requirement management tools or IDEs) to manipulate various artifacts being crucial for the process. In turn, these activities and tool interactions are not directly captured in the process models since they are too fine-grained. Thus, a dichotomy between the planned and the actually executed process may exist.

Process Dynamicity (Prob:ProcDyn). Reality has shown that project enactment not always happens exactly as planned [BDS+99, RHD98]. A planned process is a good starting point. However, if the real course of a project deviates from this plan, it will be a challenge to keep the plan in line with reality [ReDa98]. Most contemporary PAIS still rely on rigidly predefined workflows and only feature rather limited abilities to cope with such dynamic changes [Pevd06, ReWe12]. Thus, the planned and the actually executed process diverge more and more, and the former becomes irrelevant over time.

In the following, we present a scenario relating to problems with process model implementation in SE projects. The scenario does not deal with a concrete use case or situation, but rather with a specific process model and issues relating to its automatically supported implementation. For this purpose, we chose the OpenUP [EcFo15] for several reasons:

- **Availability**: OpenUP is a freely available derivate of the Unified Process. It requires no licensing fees or other costs.
- **Understandability**: OpenUP is clearly structured and the Eclipse Foundation provides comprehensive documentation free of charge.
- **Comprehensiveness**: OpenUP covers both abstract and operational process areas including workflows ranging from abstract phases of a project to concrete developer workflows.
- **Contextual relations**: OpenUP specifies a rich set of entities that relate to real entities or persons in an SE project like artifacts, tools and roles.
- **Comprehensive human tasks**: OpenUP features various different activities and tasks of different granularities for humans.
- **Comprehensive support features**: OpenUP comprises a rich set of supportive artifacts like checklists or guidelines.
OpenUP is manually implemented. In particular, the whole process definition exists as web pages [EcFo15]. When implementing OpenUP in an SE project, the involved persons must gather information manually and apply it to the project. We will use OpenUP as scenario for illustrating the following problems: the basic automated implementation of the whole model (cf. Prob:AutoProc), the establishment of connections from this implementation to the ‘real world’ (cf. Prob:ContInt), and the dynamic nature of SE process enactment (cf. Prob:ProcDyn). For the sake of illustration, Figure 4-2 shows five excerpts from the OpenUP website comprising a list of various activities, an operational workflow specification, relations of artifacts and roles, a checklist, and fine-grained activity steps.

Figure 4-2: OpenUp excerpts (adopted from [EcFo15])
These excerpts show that the OpenUP indeed comprises important and useful information to aid the SE process. However, there is neither a tool implementing or supporting this process model nor a strategy on how to achieve this with any tool in place. Thus, this information remains disconnected from the real process enacted in the SE project. The information not only needs to be gathered manually by humans, it is also not tailored to the concrete project or situation. It does feature detailed information from abstract phases of a project to operation workflows. However, the latter, like the ‘Develop Solution Increment’ workflow, are rigidly predefined and not integrated with other tools or the humans in the project. Thus, support for handling unforeseen situations and adapting process enactment are also not in place.

**Unplanned Activities (Prob:UnplanAct).** The application of PAIS technology in dynamic and evolving domains such as SE is difficult [JaCo93]. Reality often diverges from rigidly pre-defined processes [McCo01, CNGM95] in that domain. In fact, process models cannot cover all workflows actually executed in an SE project. Hence, we distinguish between intrinsic workflows being part of the process and extrinsic workflows (cf. Chapter 8) being unforeseen in the latter. Such extrinsic workflows can be executed based on specific situations, but can be also recurring common tasks (e.g., bug fixing or technology evaluation). These tasks rely heavily on the current situation, remain unplanned and untraced, and may impact timely process enactment (cf. Example 4-1).

**Example 4-1 (Ad-hoc activity):**
Consider an ad-hoc activity as it was perceived during an interview conducted with a developer as part of an industrial case study. During the interview, a requirements analyst came in, telling the developer that he had to do a presentation for the customer soon. He had already received a current version of the software. However, shortly before the presentation he found a new bug endangering the success of the presentation. Hence, the developer quickly started to work on that issue, was able to fix it, and the requirements analyst received the fix via USB stick. According to the developer, such ad-hoc activities occur often, take up to half an hour, and remain untraced.

In the following, we will use the term *process coverage* to refer to the coverage of the actually executed processes in an SE project the used SE process model can cover. The models feature a list of standard SE processes. However, they do not cover a great number of activities executed in daily work in an SE project. Thus, these activities remain unplanned and untraced and can even influence the planned processes enactment. Due to these uncaptured activities the planned as well as the actually executed process can move increasingly apart from each other. Furthermore, the planned process can be delayed without exposing the reason for the delay. Finally, the unplanned activities are not guided, supported or governed. They are executed completely manually without any process or knowledge support. Example 4-2 deals with a concrete situation for such extrinsic workflows.

**Example 4-2 (Process coverage shortcomings):**
The Company uses a SE process model for standard development activities. However, there are various issues in everyday work not covered by such a model. These include activities like bug fixing, refactoring, technology swapping, or infrastructural issues. There have been efforts in The Company to model workflows for these issues in order to provide the humans with automated support and guidance. Since there are various kinds of issues with ambiguous and subjective delineation, however, it is difficult and burdensome to universally and correctly model them in advance for acceptability and practicality. Many activities may appear in multiple issues, but are not necessarily required, bloating different SE issue workflows with many conditional activities if pre-modeled. Figure 4-3 shows such a workflow for bug fixing that contains nearly 30 activities, many of them being conditionally executed for accomplishing different tasks like testing or documentation. An example is provided by static analysis activities that are eventually omitted for urgent cases. Furthermore, there are various reviewing activities, having different parameters (like effectiveness or efficiency), where the choice can be based on certain project parameters (e.g., risk or urgency). The same applies to different testing activities. Moreover, it has to be determined whether a bug fix should be merged into various other branches in the source control system.
4 Requirement Analysis

As many decisions in the workflow rely on properties of the situation, many activities could be excluded prior to enactment as each situation requires another workflow that marks a subset of the workflow shown in Figure 4-3. However, the situational information for making such decisions is not always in place and gathering it would require additional efforts from humans. Another option, modeling many smaller workflows for different situations is also problematic, as the matching workflow for each situation would have to be determined manually. Additionally, that solution would result in a large number of modeled workflows making the selection of them even more inefficient. Finally, many of the activities and even whole fragments of the workflows would appear in multiple workflows resulting in redundant modeling. Usually, such redundant model fragments are difficult to maintain and might lead to diverging models over time [WRMR11].

Uncoordinated Collaboration (Prob:Collab). In a complex project, there are always persons, tools, activities, and artifacts related to each other [JYW07, SQTR07]. This fact implies that an activity a person executes to change an artifact can have an impact on other artifacts, which again has an impact on the activities of other persons. As example of a relation consider architectural specifications and relating source code artifacts. As some of these activities may be covered by the process, while others are not, this can result in problematic artifact states if many related adaptations by different humans are applied in an uncoordinated manner. As aforementioned, collaboration remains one of the biggest challenges in SE projects [Dust04] and teamwork is still not adequately supported [LeBo07].

As the sizes of companies, departments and projects grow, communication between collaborating humans and teams becomes increasingly challenging. Humans are often involved in multiple projects in parallel, each of them having its own artifact base the humans work on. Hence, humans are often switching between the projects and concurrently manipulate artifacts of these different projects. In turn, this can lead to a myriad of different problems relating to the artifacts or tasks conducted. Example 4-3 concretizes this.

Example 4-3 (Coordination shortcomings):
Being a growing small to medium sized enterprise (SME), The Company suffers from the inability to satisfy increased coordination needs. Team sizes are growing and various projects are executed in parallel. Humans often have to switch between different projects and within each project larger numbers of humans are working on the same artifacts. Without additional coordination effort things might be easily forgotten.

One concrete problem reported by developers is related to frequent project switches. A person doing this in such a multi-team / multi-project environment must manually gather context information after a switch in order to work effectively: Which assignment has to be processed for which project? What
are potential milestones and deadlines? What is the state of the currently processed assignment? What are upcoming activities to complete it?

Two other problems relate to cooperatively working on the same artifact base. As the first issue in this situation, activities and accompanied changes to artifacts often remain unnoticed by other humans. For example, if two teams (e.g. a development team and a test team) are working on the same source code artifacts they might want to get informed about changes of them. Such information is often transferred manually and is therefore prone to omissive errors.

The third problem directly relates to the artifacts and their relations: Artifact changes often imply certain follow-up actions that are hitherto coordinated manually. Figure 4-4 depicts a scenario detailing this: It deals with a source code artifact being part of an interface component: since the file belongs to an interface component, the applied changes might not only affect the unit tests of the file, but also other artifacts such as the architecture specification or integration tests. Usually, these additional activities are neither covered by the SE process nor governed by any workflow; manual coordination can lead to impacts being forgotten and result in inconsistencies, e.g., between the source code and the tests or specifications. The fact that these activities belong to different project areas with often also different responsible persons makes this even more difficult. Even if not forgotten, follow-up actions could benefit from automated governance and support. Furthermore, it can be difficult to determine which stakeholder should be informed about which change and when, especially considering the dynamic and diverse nature of the artifact-to-stakeholder relationship and various information needs.

**Process Exceptions (ProbProcExc).** During project enactment, unforeseen and exceptional situations occur as the SE process is not fully predictable [Schw97, BDS+99]. In turn, this poses a big challenge to any framework seeking to provide holistic process support for such projects. Contemporary workflow management technology has limited capabilities in this area, only dealing with exceptions directly relating to activities [ReWe12, RAH06]. In practice, process exceptions are often not that simple and also not easily detectable. Further, they may relate to processed artifacts even without the person working on these artifacts noticing them. Finally, to select an exception handling suitable for both the situation and person is challenging.
Complex exceptions are not related to the malfunction of a single tool or program, but to the prescribed process or other more complex coherences in an SE project. Such exceptions can relate to activities being part of the prescribed process or to others being extrinsic to the latter. They may also relate to artifacts processed in the course of the project, even if all activities seem to be executed as intended. Such exceptions are difficult to detect and handle even if The Company uses a PAIS providing process implementation support. In the following, two concrete examples (Example 4-4 and Example 4-5) are provided to illustrate this.

Example 4-4 (Exception handling shortcomings):
The Company uses an SE process model. However, there is no tool in place to govern, support or enforce the executed process. Consider the following situation: A developer creates new code as intended as part of a project: Assume that it is prescribed by the process of that project that he shall create and execute a unit test for this code. As the process is neither enforced nor supported, however, he can intentionally or unintentionally omit these activities. If such things happen, often a growing portion of the code remains untested. This, in turn, endangers reliability of the code base.

A second scenario deals with a known bug in a source code artifact that is, for example, reported by a customer, tracked in a bug tracking software. The bug is then assigned to a developer who shall fix it. When applying a bug fix to the source code file, the removal of the defect might unintentionally introduce other problems to that file. For example, source code complexity might increase if multiple humans applied “quick and dirty” fixes. Thus, the understandability and maintainability of that file might drop dramatically and raise the probability of further defects.

Non-optimal Quality Management (Prob:QualMan). Another problem affecting many SE projects concerns the quality of the software produced [Jone10]. Hence, quality assurance is a crucial factor for any SE project. However, in many SE projects, quality assurance is understood as applying some bug fixes at the end of the project when time allows for this. Studies have shown that this is ineffective and quality measures should be applied systematically during SE project enactment [Hami88, SHK98]. In particular, this requires proactive as well as reactive quality measures. The challenge is to effectively and efficiently integrate the application of these quality measures with the SE process. Concrete issues include the following: quality management is often considered a ‘nice to have’ discipline creating no additional value. Very often it is difficult to integrate quality management activities with the course of the standard SE process. Furthermore, quality management is often only executed in a reactive fashion applying fixes for known bugs. No quality goals are defined that could be proactively supported to prevent the occurrence of bugs. Example 4-5 illustrates such a situation.

Example 4-5 (Quality management shortcomings):
The Company, being a growing SME, starts with various efforts to support reproducibility of project enactment as well as product quality with process management and quality management. As aforementioned, a process model for the SE process is used. Furthermore, as the number of bugs reported by customers shall decrease, quality management tools are applied. This includes bug trackers and static code analysis tools. However, both quality and process management are not well governed or supported. Quality goals are not defined for projects and thus, no proactive quality management can be applied. There is no real awareness of the execution of planned development activities. Thus, it is difficult to integrate quality management activities into the standard SE process. Static code analysis is only used at the end of projects and due to the time pressure often present in that situations, many detected problems still remain unsolved.

Unutilized Knowledge (Prob:Knowl). The creation and modification of software is a complex and knowledge-intensive task [RaT99] and software is an intangible asset. It involves knowledge from different sources, all of which are crucial for the success of the task [LiRu02]. This includes information on the process, the coding style and other specifics of the company, the used framework or area (frontend or backend development), and so forth. Companies often neglect this fact and do not implement proper knowledge management. Even if some knowledge store is implemented, knowledge
retrieval and effective knowledge usage remain an issue [SBBK08]. This often leaves software engineers without all required knowledge and thus makes their work ineffective and error prone.

As mentioned in Chapter 1, wikis are often used to let project participants store specific knowledge. They make recoding of information easy, but management and retrieval of the latter often constitutes a challenge. This is aggravated by the fact that knowledge related to SE is usually context-dependent meaning that it must match the properties of the situation and the involved person. As scenario for illustrating knowledge management shortcomings a situation comprising different information needs in The Company is presented in Example 4-6.

<table>
<thead>
<tr>
<th>Example 4-6 (Knowledge management shortcomings):</th>
</tr>
</thead>
<tbody>
<tr>
<td>As a growing SME, The Company frequently hires new developers. The latter get training at the beginning to ensure that they can work effectively as early as possible. However, they still might not have a great share of the concrete information relating to projects, tools or the process. For example, this might include information about the coding style applied in The Company. Also, specific process-related information might be recorded somewhere, but the new developer might not know exactly when and where to acquire that information. Another example are technical specifics about the project he starts to work in as, for example, how source control management is applied including information about different development branches and the commit procedure. Lacking all that information, there is a high probability that the developer will cause many issues when he starts working.</td>
</tr>
</tbody>
</table>

4.2. Basic Requirements

This section gives an overview on the high level requirements for a tool providing automated support for the SE process. We elicit these requirements based on two foundations: First, we refer to the problems discussed in Chapter 1, including their support by literature. Second, we refer to our observations from practice as indicated by the scenarios in this section. As aforementioned, the basic requirements listed in the following will be detailed with sub-requirements in the relating chapters of this work.

- **Requirement Automated Process (R:AutoProc):** The most basic requirement to a tool enabling holistic SE project support is to provide SE process support. Related problems have been discussed in Prob:AutoProc. This includes the automatic implementation and enactment of processes in the tool.
- **Requirement Context Integration (R:ContInt):** As elucidated in the problem statement (cf. Prob:ContInt), there is a myriad of contextual information in the project having a significant impact on process enactment. For example, context information plays an important role for collaboration, quality management, or exception handling. Therefore, a tool aiming at holistic SE project support must have facilities to integrate process enactment with context data.
- **Requirement Dynamic Process (R:DynProc):** SE projects are dynamic as already shown in the problem statement (cf. Prob:DynProc) and confirmed by the scenarios in this chapter (e.g. relating exception handling or quality management). Therefore, a tool supporting these projects must be capable of coping with dynamically changing situations and aligning the process with their properties.
- **Requirement Process Coverage (R:ProcCoverage):** SE process models cover many workflows. However, as shown (cf. Prob:UnplanAct), they disregard many activities and processes executed dynamically as part of everyday work. When aiming at true holistic support for SE projects, a tool must include these workflows and activities as well.
- **Requirement Coordination (R:Coord):** SE projects comprise numerous different areas, actors, and artifacts. Projects are executed in parallel and multiple persons work on the same artifact base. Activities, roles and artifacts have relations to each other and collaboration is not easy to maintain. This can lead to various issues as discussed (cf. Prob:Collab). A tool providing holistic SE project support must be aware of such connections and be capable of managing coordination and collaboration in such a project.
• **Requirement Exception Handling (R:Exc):** In an SE project, many unforeseen problematic situations might occur (cf. Prob:ProcExc). Newly created problems might not directly show up and be obscured from their creator. A tool aiming at SE project support should have facilities to detect such complex exceptions and automatically assist humans in handling them.

• **Requirement Quality Management (R:Qual):** Quality management is a crucial as well as an underestimated part of SE projects. This has been agreed upon in literature (cf. Prob:QualMan) and our practical observations confirmed this, as well. The intangibility of the produced asset (the code) makes it difficult to even be aware of its state. Furthermore, if quality problems are detected, counter measures must be executed in alignment with the process. If a tool shall provide holistic support for SE projects, it must be capable of supporting these complex tasks.

• **Requirement Knowledge Management (R:Know):** As SE projects are knowledge-intensive undertakings with a multitude of different complex information, the latter is not easy to manage. This is confirmed by literature (cf. Prob:Knowl) and practice (cf. the scenario in this chapter). A tool aiming at holistic SE project support must enable the collection, management and dissemination of that knowledge in a process-centered and context-sensitive manner.

### 4.3. Requirements Verification

We have conducted a comprehensive literature study comprising many aspects of SE projects. One reason for this was to support the elicitation of requirements for a framework providing comprehensive support for SE projects. However, the study also included a myriad of tools and approaches aiming at the support of different aspects of SE projects. In this section we discuss how the results of this study can be used to verify the requirements we have elicited.

We have examined approaches of different areas that relate to the topics identified as important for this thesis. An important area are Software Engineering Environments (SEE). These are tools aiming at comprehensibly supporting SE projects. In this area, we have examined various CASE (Computer-Aided Software Engineering) tools (e.g., [EKS93]), Process-Centered Software Engineering Environments (PCSEEs, e.g., [BFGL94, CLH95, BEM94, Barg92b]), modern SE Environments (e.g., [dZR+04, JYW07, HaLa10, WEB+09, dFOT10]), and other contemporary SE approaches (e.g., [BWHK12, PVPB12, GTS10, CAG12]). For a thorough discussion we refer to Chapter 6.

Another important area are processes and their automated enactment. In this area, we have examined WfMS/PAIS (e.g., [Cumb07, Inta15, vdtH05]), process configuration approaches (e.g., [RSS10, Gott09, HBR10, LDH09]), artifact-centric process approaches (e.g., [BHS09, KüRe11a]), process adaptation approaches (e.g., [Wesk01, MOO00, WRWR09, MTS08]), semantic process annotation approaches (e.g., [Mich15, PDB+08, AFKK07, BGM07, ABB+07]), declarative process approaches (e.g., [Pesi08]), and approaches for contextual process integration (e.g., [LH+06, DGD07]). Besides that we also took into account context modeling approaches like [KMK+03, FaCl04, GPZ04] (see Chapters 7 and 8 for details). In the context of dynamic processes, we have also reviewed approaches for process exception handling (e.g., [MGR04]). Such approaches are discussed in more detail in Chapter 11.

We have also examined various approaches from other areas identified as important for SE projects. These are knowledge management approaches (e.g., [BDi08, Liao03, BWT04]) and collaboration and coordination approaches (e.g., [LeBo07, BSV07, Dust04]). For a more thorough discussion we refer to Chapters 10 and 12. Furthermore, we examined different approaches for SE quality management. These included approaches for software metric application (e.g., [OfJe97, GKM02]), software measurements tools (e.g., [SeJe06, LiZh05]), and approaches for the Goal-Question-Metric (GQM) technique (e.g., [FaWu09, STS05, HuFa05]). For more information on these see Chapter 9.
Relevance and Completeness

The various approaches examined show the relevance of the elicited requirements for SE projects relating to various application cases. The need for tool support for SE processes (R:AutoProc) is confirmed by the various SEE approaches. Automated process support in general is the target of countless PAIS and WfMS approaches. The importance for contextual integration (R:ContInt) is discussed by various SEE as well. According to them, such information comprises artifacts, various types of knowledge, or persons and their interaction.

As many approaches confirm, processes also need to be handled dynamically (R:DynProc). On one hand, various SEE cover this topic and provide capabilities to change running processes. On the other, there exist a myriad of approaches for configuring or changing processes. Such approaches even offer the capability to automatically change running processes. This is often used for handling exceptions occurring during process enactment. This also confirms that process exception handling (R:Exc) is a relevant topic for a tool that automates processes. In addition to that, much attention has been paid to unstructured processes that are not pre-planned as part of a process model. Constraint-based and declarative process approaches deal primarily with such processes. This confirms the importance of capabilities of a tool to also cover such processes (R:ProcCoverage).

A crucial factor for any SE projects is quality management (R:Qual). This is confirmed not only by approaches explicitly dealing with this topic, but also by many SEE approaches that take into account source code artifacts and aim at supporting and improving their management. The same applies for collaboration and coordination support (R:Coord). Many specific approaches stress the importance of this topic for SE. In addition to this, various SEE also integrate facilities to support this. Another important area for SE projects is knowledge management (R:Know). This is confirmed both by various dedicated approaches as well as the integration of knowledge management capabilities in many SEE.

The goal of our approach cannot be to solve each and every problem in SE. Therefore, the requirements also cannot be considered as complete for SE. However, we can show that the selected requirement areas cover important aspects also mentioned in a myriad of other approaches and that those approaches do not discuss or cover important areas that we have omitted. SEE have existed for multiple decades now and each of them covers different areas and capabilities. However, topics that repeatedly occur are the following: processes, with a strong focus on dynamicity as well as people and collaboration aspects. Furthermore, they deal with various entities that can be considered as context to the tools and processes, as, e.g., artifacts and people. Furthermore, they deal with different kinds of knowledge that is crucial to SE projects. To the best of our knowledge, these SEE do not cover other core aspects that we have omitted in our discussion. Contemporary SE approaches, however, show two trends gaining momentum: cloud-based SE and global SE, which both correspond to each other. We have decided to put this not to focus in this work as it can be considered primarily as a technical aspect. Our requirement areas are more focused on content-related issues of SE projects.

Relatedness and Generalization

The various approaches we have reviewed not only show that our requirements are relevant for SE projects, they can also serve as indicator that they are related to each other and that their combination is essential for successful SE projects. Again, SEE serve best as comparative approaches as they share the same goal as our approach. These approaches often have a strong focus on the SE processes and they connect it with various other areas. None of them combines all of them but multiple approaches respectively combine it with contextual data, collaboration support, knowledge management, and quality management relating the SE artifacts. For a fine grained discussion of the different features of different approaches see Chapter 15.

In the first place, our approach is targeted at SE projects. This means neither the approach nor its requirements can be automatically seen as generally applicable for all domains. However, SE is a vast field and not necessarily a distinct domain. Software is developed in various domains like the
automotive or the healthcare sectors. Furthermore, in SE slightly different approaches to project and process management are utilized. Some projects apply huge and heavyweight process models with hundreds of controlled artifacts. Others apply lightweight and agile approaches that prescribe hardly anything and mostly rely on people. The various approaches and tools we have reviewed also show this diversity. They are applied in various domains like the automotive or the healthcare sectors or are applied in projects regulated by state authorities. Furthermore, they involve all the different approaches to project and process management that are prevalent in SE (e.g., Scrum or V-Model XT). Therefore, we assume that the requirements we elicited are applicable for the vast majority of SE projects regardless of their domain or process approach. Furthermore, in the evaluation of this thesis, we will show the application of our approach to slightly different process approaches for SE and also to a process of the software modernization domain.

4.4. Summary

This chapter elicited eight basic requirements for a tool that aims to provide holistic project and process support for SE projects (cf. Table 4-1). These requirements are aligned with the abstract problems discussed in Section 1.1. To further illustrate the requirements and demonstrate their practical relevance, a set of concrete scenarios was presented, which will be taken into account for validating the developed approach (cf. Chapter 13).

</table>

The requirements are categorized as follows: Basic functionality requirements cover the basic facilities a tool must provide to holistically support the SE process. They do not refer to functionalities providing additional value to humans. However, they are crucial and constitute the basis for the other functionalities. Extended functionality requirements cover functionalities that enable general automatic and contextual support for humans in various areas of a project. The third area refers to specific functionality requirements and is targeted to specific areas of SE projects. Note that not all possible areas of an SE project are covered in this work as this would go beyond the scope of this thesis. Rather, the focus is on two areas of knowledge and quality management as these have been proven important parts of each SE project.
Part IV

Conclusion
16. Summary and Outlook

SE projects are complex, long-running, and knowledge-intensive, depending on a myriad of different factors that are not easily controllable. Furthermore, the developed product, i.e., the software, constitutes an intangible asset whose quality state cannot be measured easily. This places pressure on the knowledge workers in SE projects. Many aspects of the projects, their process, and the produced product are implicitly managed and prone to forgetfulness or other errors.

Due to these various issues, SE projects have always been problematic. From the beginning of SE until today many projects have exceeded their budgets and schedules, delivered low-quality erroneous software, or even failed completely. To make projects more repeatable as well as to support their execution, SE process models have been developed. This started in the 1970s with classical models such as the Waterfall Model [Royc70] or the Spiral Model [Boeh88]. However, these SE models often were too rigid and could not mirror the dynamic SE project execution in reality. More recently, the agile trend took account of this property and agile processes like Scrum [ScBe01] have been popularized. These developments have improved the situation, but still many projects struggle with time, resources and software quality.

A remaining problem concerns the operational support for the projects, their processes, and, first and foremost, the involved software engineers. Projects and their processes are often planned up-front and their execution does not match this plan, resulting in an ever-growing gap between plan and reality. Software engineers utilize a large set of SE tools supporting different tasks like IDEs, source control management systems, or bug trackers. However, the complexity of SE projects keeps growing; e.g., the sizes of projects keep growing, the different tools are often rather complicated, and their number grows as well. Moreover, holistic SE support is missing. Tools may comprehensively support a specific task, but are not connected well to the other tools. Much is still left to the software engineers without providing any guidance to them. Although their collaboration is crucial, it has not been properly supported or governed yet. Crucial project knowledge remains only in the heads of the humans, and is not properly stored, managed and disseminated among the project participants.

This work presents a holistic approach to support both SE projects and, especially, SE processes. In the following we will briefly summarize the core contributions of this thesis:

**Automated process support:** The CPM framework provides an infrastructure for comprehensive SE project and SE process support. It unites different state-of-the-art technologies encapsulated in loosely-coupled components. The set of components comprises, among others, dedicated components for process enactment, context integration, or knowledge management. Thus, it not only enables the modeling and enactment of workflows, but also the extension of the workflows with a myriad of additional data sets that support the implementation of entire SE process models. As SE process enactment is known to be complex and dynamic, the CPM framework comprises additional basic components, enabling the simple definition and execution of configurable automatisms to support humans in recurring standard situations. It further enables CPM to cope with various dynamic situations whose exact configuration and course might not be estimated a priori.

**Context integration:** The execution of an SE project and SE process depend on various contextual factors, like the properties of the executing humans or the states of involved artifacts. The CPM framework integrates different facilities to deal with such information. First, it features a set of sensors that can be integrated into various SE tools to automatically gather information. Second it enables the automatic processing of such information to derive meaningful information from the numerous events happening in an SE project. Third, by an extended process specification, it enables the direct and tight integration of process enactment with the context of the project.
Summary and Outlook

**Process dynamicity:** SE project execution is rather dynamic and mostly differs to what was planned. Therefore, the CPM framework incorporates dynamic processes. Thus, the different workflows executed in the context of an SE process can be dynamically changed during run-time to adhere to changing situations. However, as the projects comprise many different areas and the set of influential context factors is high, it can be challenging for a human to apply a process adaptation on account of this data. To support this, the CPM framework not only enables manual process adaptations, but also automated and context-aware ones.

**Extrinsic process coverage:** Process models cover a substantial portion of the work done in an SE project. However, many workflows cannot be covered by them for various reasons. Such workflows are characterized by three main properties. First, they cannot be completely foreseen. Second, they are rather dynamic. Third, they depend on their context even more than the ones belonging to the SE process models. Therefore, the CPM framework incorporates a declarative and dynamic way of modeling such workflows that allows directly integrating contextual influences. Furthermore, it enables a uniform way of enacting them similarly to imperative workflows.

**Quality assurance integration:** Quality assurance is a crucial part of any SE project. However, many projects struggle with bad source code quality. Therefore, the CPM framework integrates facilities to automatically measure the source code quality and to distribute software quality measures to the software engineers in case of quality problems. This comprises a monitoring of the human activities to be able to find the right point in the process for inserting a software quality measure as well as a dynamic tailoring of the latter to select the right measure for the right human and situation. Finally, the CPM framework automatically assesses the applied measures to optimize the measure distribution over time.

**Collaboration and coordination:** The collaboration of the involved knowledge workers constitutes a crucial part of any SE project. This collaboration might get complicated and error-prone in large projects. Therefore, the CPM framework integrates facilities to support such collaboration in two ways. First, it fosters automated information distribution, informing one human about important changes to their environment as, for example, the status of the activities of their colleagues. Second, it is capable of automatically initiating follow-up activities for certain changes in a project impacting other humans.

**Process exception handling:** In an SE project many things do not work exactly as planned. Many exceptions might occur relating to the process, its activities, the involved humans, or the processed artifacts. The CPM framework uses its contextual infrastructure to detect as many of these complex exceptions as possible. Furthermore, it is capable of automatically determining an exception handling procedure and distributing it to the appropriate human to apply it.

**Knowledge provisioning:** SE projects largely depend on the knowledge of the humans involved possess. However, the management and distribution of such knowledge remains a challenge. The CPM framework fosters gathering, storing, and managing of such knowledge. Furthermore, due to its process- and context-related capabilities, it is capable of automatically distributing knowledge to project participants that matches their current situation and problems.

The CPM framework delivers a set of functions we believe to be unique. It unites various areas like dynamic process management, human assistance, and quality management. In these areas, however, there exist specific approaches as well. For example, [HMMR14] focuses on supporting the human by providing process visualizations and additional information. Others support enactment of parts of processes for specific humans based on process views [KoRe13]. The knowledge worker is supported by various approaches as well. Examples include flexible checklist support [MuRe14] or mobility support of knowledge workers by approaches like [PMR14]. Another area is quality management for processes with approaches like [LoRe15]. All of these approaches have their strengths and go beyond the capabilities of the CPM framework in a specific area. The main strength of the latter is, however,
is the comprehensive, applicable and usable integration of a large set of different areas to better support humans in SE projects.

The CPM framework presented in this work solves many problems of SE projects as it provides holistic SE project and SE process support. However, there exist various options for further improving and extending the approach. In the following we will highlight some of the most important ways, the CPM framework might be extended.

We have already discussed and created a set of extensions and additions to the CPM framework not directly being part of this work. One of these extensions is related to the modeling of the contextually extended processes. In the CPM framework, humans model the workflows directly in the WfMS and the different extensions in a web GUI. Such modeling would be simplified if humans had modeled the complete process in one tool and notation. To enable this, we have already created a preliminary approach for a SE workflow language comprising all necessary properties and can then be automatically transformed into the workflows of a WfMS and the additional contextual extensions applied in the CPM framework. For further reading on this topic, we refer to [GOR11a].

In SE, the assessment of processes and their improvement is a crucial topic as well. Process assessment and improvement approaches like ISO 15504 (SPICE) and CMMI (for more information regarding these two, see [Wall07]) have therefore received much attention. Thus, an integration of such approaches into an approach for SE project and SE process support is desirable. We have already created such an extension of the CPM framework enabling the semi-automatic assessment of an executed SE process with models like CMMI or SPICE (see [GOR12e, GOR13]).

Another interesting option will be the application of the CPM framework in other domains as standard SE projects. In the future, with a set of specific other sensors, an application in other knowledge-intensive domains becomes possible. We have already started to investigate such options. As we did not have the resources to develop a completely new set of sensors, we investigated a type of project that can rely on the sensors we already have. In [GOR14] we have discussed the application of the CPM framework in the context of specific software modernization projects.

The preliminary evaluation showed that our concepts have great potential for really supporting SE projects. Regarding the industrial application, however, a larger scale industrial evaluation remains as a future task. To enable the latter, we will need to add various features. For being usable in large scale productive projects, a consistent privacy approach will be necessary. Furthermore, some of the applied technologies will have to be adapted to ensure performance and scalability in larger industrial environments.

Appendices
A. Ontology

The ontology has been modeled and accessed only using the Protégé ontology editor. In the following, we will present a small set of exemplary concepts of the ontology as modeled in OWL XML. Some of the properties have been renamed due to the fact that names in an OWL ontology are unique and one such property as e.g. ‘workUnitContTempl’ should not be used to connect a work unit container template to a project template and to a work unit template but rather two distinct properties are required here, in this case, ‘workUnitContTemplat’, and ‘containingWUCT’.

A.1. Imperative Process Concepts

This section presents the discussed concepts for the imperative processes.

A.1.1. Template Concepts

This section presents the template concepts. First, Figure A-1 gives an overview of them (barely readable and just as visual overview) directly from the Protégé ontology editor. After that, for an exemplary concept, the XML definition from the ontology is shown (cf. Listing A-1). Keep in mind that the properties of the concepts are not directly part of the concepts. However, the restrictions on a selection of properties can be seen.

A.2. Declarative Process Concepts

This section presents an excerpt of the concepts related to the declarative modeling approach from Chapter 8 (cf. Listing A-3 and Listing A-4) preceded again by a visual overview in Figure A-3. The building block template shows only one restriction because the cardinality restrictions on properties ‘info’ and ‘problem’ are realized in its super concept, the declarative modeling element. The declarative container template, in turn, is a sub concept of the declarative modeling element and the work unit container template.

B. Conceptual Framework

In this appendix, we discuss the concepts of the CPM framework and provide exemplary formal definitions. The appendix is separated into different sections to improve readability. First, different concepts for entities are shown followed by concepts for consistency checks and algorithms.

B.1. Entity Concepts

In this section, concepts for various CPM entities are discussed. For the sake of brevity we only show a selection of interesting concepts.

B.1.1. Basic Concepts

This section deals with the basic concepts of the CPM framework. We only show a selection of the definitions of these concepts. However, for completeness, Table B-1 gives an overview about all of these basic concepts. Extensions for topics like quality management are not included here.

</tbody>
</table>

Two properties shared by all concepts are type and name. The former denotes the type of concept, like work unit container, whereas the latter is a unique identifier for each concept. As both are common for all concepts, they are not further mentioned in the definitions.
Work Unit Dependency

As discussed in Chapter 7, we have added a new dependency between different workflows to the one already existent in WfMS. The template concept for this new dependency is defined in Definition B.1:

**Definition B.1 (Work Unit Template Dependency)**

An *work unit template dependency* is a tuple \( \text{workUnitTemplDep} = (\text{type}, \text{name}, \text{source}, \text{target}, \text{async}, \text{behavior}) \) where

- \( \text{source} \in \text{WorkUnitTempls} \) is the source depending on \( \text{target} \).
- \( \text{target} \in \text{WorkUnitTempls} \) is the target the source depends on
- \( \text{async} \in \text{BOOLEAN} \) indicates whether the dependency is asynchronous or synchronous.
- \( \text{behavior} \in \{\text{firstShot}, \text{lastShot}\} \) indicates when the dependency is satisfied.

\( \text{WorkUnitTemplDeps} \) describes the set of all definable work unit template dependencies.

The work unit template dependency connects a work unit template \( \text{source} \) with a work unit template \( \text{target} \). When a work unit, which is based on the \( \text{source} \) template, comes to enactment, the work unit container containing the \( \text{source} \) work unit will be created (if it is not already in place). If the \( \text{async} \) property is set to FALSE, the termination of the \( \text{source} \) will depend on the termination of the \( \text{target} \). As the target is a work unit in that case, it might be executed more than once in a LOOP. Therefore, the \( \text{behavior} \) property governs whether the source terminates with the first or last termination of the target.

Both dependencies have a related stateful individual concept capturing one individual enactment of the workflows defined by the templates. The work unit dependency (cf. Definition B.2) allows for storing the information whether its target has been executed using the property \( \text{finalized} \). As the target is a work unit it might have multiple iterations. Therefore, this dependency has two properties, one indicating that the target has been executed (\( \text{executed} \)), the other indicating that the final execution of the target has happened (\( \text{finalized} \)).

**Definition B.2 (Work Unit Dependency)**

An *work unit dependency* is a tuple \( \text{workUnitDep} = (\text{type}, \text{name}, \text{source}, \text{target}, \text{async}, \text{behavior}, \text{executed}, \text{finalized}, \text{basis}) \) where

- \( \text{source} \in \text{WorkUnits} \) is the source depending on \( \text{target} \).
- \( \text{target} \in \text{WorkUnits} \) is the target of the dependency the source depends on
- \( \text{async} \in \text{BOOLEAN} \) indicates whether the dependency is asynchronous or synchronous.
- \( \text{behavior} \in \{\text{firstShot}, \text{lastShot}\} \) indicates when the dependency is satisfied
- \( \text{executed} \in \text{BOOLEAN} \) indicates if the target has been executed at least once
- \( \text{finalized} \in \text{BOOLEAN} \) indicates if the target has been executed for the last time
- \( \text{basis} \in \text{WorkUnitTemplDeps} \) is the template that \( \text{workUnitDep} \) is based on

\( \text{WorkUnitDeps} \) describes the set of all definable work unit dependencies.

Human Activity Management

The human activity concepts (assignment, assignment activity, atomic task) require a particular set of runtime properties; therefore, we have added individual concepts for them. In the following we show Definition B.3 for the assignment.

**Definition B.3 (Assignment)**

An *assignment* is a tuple \( \text{assign} = (\text{type}, \text{name}, \text{responsible}, \text{assignActSet}, \text{workUnitCont}, \text{basis}, \text{state}, \text{guidanceSet}, \text{plannedStart}, \text{plannedEnd}, \text{actualStart}, \text{actualEnd}, \text{area}, \text{contentInfo}) \) where

- \( \text{responsible} \in \text{Resources} \) is the resource that is responsible for assign.
- \( \text{assignActSet} \) is a finite set of human activities with \( \text{assignAct} \in \text{AssignActs} \) that are crucial to complete the assignment.
- \( \text{workUnitCont} \in \text{WorkUnitConts} \) is the work unit container assign is attributed to.
- \( \text{basis} \in \text{AssignTempls} \) is the assignment template assign is based on.
- state ∈ \{Inactive, Active, Finished\} is the state of assign.
- guidanceSet is a finite set of guidances(cf. Chapter 12) used to support assign.
- plannedStart ∈ DATETIME is the planned start time for assign.
- plannedEnd ∈ DATETIME is the planned end time for assign.
- actualStart ∈ DATETIME ∪ NULL is the actual start time for assign or undefined.
- actualEnd ∈ DATETIME ∪ NULL is the actual end time for assign or undefined.
- area ∈ Areas defines the concrete area assign is attributed to.
- contentInfo ∈ STRING contains information for the human on assign.

Assigns describes the set of all definable assignments.

In order to keep track of its planned and actual execution, the assignment has four properties storing its planned and actual start and end times. In addition, it contains information on the assignment useful for the human processing it (contentInfo) and relations to guidances (cf. Chapter 12) for further support. Finally, it has a finite set of states whose transitions are depicted in Figure B-1.

![Figure B-1: Assignment states](image1)

When a work unit container is created, its related assignment is created with state ‘Inactive’ as well. It then enters state ‘Active’ when one of its assignment activities is started by the human. If he switches to another assignment, it becomes inactive again until he switches back to it. The assignment enters its final state ‘Finished’ when its work unit container is finished. The assignment activities that are part of the assignment have similar properties as well as a finite set of states. The transitions between the states are depicted in Figure B-2.

![Figure B-2: Assignment activity states](image2)

When an assignment is created, the related assignment activities get created, having state ‘Created’. When the work unit related to the assignment activity starts, the activity is available for the human, therefore it enters state ‘Inactive’. When the human starts processing it, it becomes ‘Active’. If he switches to another assignment it becomes ‘Inactive’ again until he switches back. When he finally completes it, it enters final state ‘Finished’.

The assignment activity is the planned human activity with the finest granularity in the CPM framework. However, it has connections to the more fine-grained activities, the atomic tasks. As opposed to the other activity concepts, the atomic task has no properties for planned times, but an actual start and end. However, atomic tasks are fine-grained and our experiences in real projects have shown that while processing an activity, a human frequently switches between the different tasks. Therefore, not only the absolute start and end times are recorded, but the overall duration
The atomic task also has a set of states whose transitions are depicted in Figure B-3.

When an assignment activity is created, the corresponding atomic tasks (as defined by the template concepts) are also created and enter state ‘Inactive’. A task enters state ‘Active’ when the CPM framework detects its enactment or the human explicitly selects it. It becomes inactive again when another task is selected in the same way. From both states, there is a transition to final state ‘Finished’ in case the human finishes the corresponding assignment activity.

Artifact Management

Artifacts being part of the SE process as well as their mutual connections cannot be modeled properly within a WfMS using the data elements being part of the workflows. To add facilities to model artifact structures, we consider the concept of the project component template (cf. Definition B.4).

Definition B.4 (Project Component Template)

A project component template is a tuple \( \text{projCompTempl} = (\text{type}, \text{name}, \text{reference}, \text{subCompSet}, \text{superCompSet}, \text{roleTemplSet}, \text{responsibleRoleTempl}, \text{reqCompTemplSet}, \text{stateSet}, \text{relatedCompTemplSet}, \text{areaTempl}, \text{compTemplType}) \) where

- \( \text{reference} \in \text{STRING} \cup \text{NULL} \) is a reference to the template of a real artifact (e.g., Specification) or undefined.
- \( \text{subCompTemplSet} \) is a finite set of project component templates that are subordinate to \( \text{projCompTempl} \) with \( \text{projCompTempl} \in \text{ProjCompTempls} \).
- \( \text{superCompTemplSet} \) is a finite set of project component templates with \( \text{projCompTempl} \in \text{ProjCompTempls} \) that the \( \text{projCompTempl} \) is subordinate to.
- \( \text{roleTemplSet} \) is a finite set of role templates with \( \text{roleTempl} \in \text{RoleTempls} \) used to define one or multiple human roles according to \( \text{projCompTempl} \).
- \( \text{responsibleRoleTempl} \in \text{RoleTempls} \) defines the main role template according to \( \text{projCompTempl} \).
- \( \text{reqCompTemplSet} \) is a finite set of project component templates that \( \text{projCompTempl} \) requires with \( \text{reqCompTempl} \in \text{ProjCompTempls} \).
- \( \text{stateSet} \) is a finite set of \( \text{STRINGS} \) used to define the possible states for \( \text{projCompTempl} \).
- \( \text{relatedCompTemplSet} \) is a finite set of project component templates that has a content-related relation to \( \text{projCompTempl} \) with \( \text{projCompTempl} \in \text{ProjCompTempls} \).
- \( \text{areaTempl} \in \text{AreaTempls} \) is the area template \( \text{projCompTempl} \) is associated to.
- \( \text{compTemplType} \in \text{STRING} \) is concretization of the type of \( \text{projCompTempl} \).

The project component template is an abstract concept that generalizes more concrete sub concepts. Therefore, \( \text{ProjCompTempls} = \text{ArtifactTempls} \cap \text{SectionTempls} \). \( \text{ArtifactTempls} \) and \( \text{SectionTempls} \) are disjoint subsets of \( \text{ProjCompTempls} \) that are defined by:
- artifactTempl ∈ ArtifactTempls is a project component template for which the following applies:
  \( \text{artifactTempl.reference} \neq \text{NULL} \land \text{artifactTempl.subCompTemplSet} = \emptyset \).

- sectionTempl ∈ SectionTempls is a project component template for which the following applies:
  \( \text{sectionTempl.subCompTemplSet} \neq \emptyset \land \text{sectionTempl.reference} = \text{NULL} \).

The project component template has a set of basic properties starting with a reference to the real entity it models (reference). In addition, it enables the definition of a set of role templates (roleTemplSet) and one role template responsible for the project component (responsibleRoleTempl). That way, a CPM framework can determine which human to inform (e.g., when there is a problem with an artifact). It further allows for content-related categorization by referring to an area template (areaTempl) and type (compTemplType). The latter might be for example ‘PDF file’ or ‘Java artifact’. Based on this type, the CPM framework can issue activities matching the project component (cf. Chapter 10). As opposed to the other concepts, the project component template allows defining a set of states the project components based on it may have during execution. This option has been introduced since many different types of artifacts in projects with a myriad of different states exist. Note that these states are not controlled by the CPM framework, but must be set by humans during enactment.

Another feature of the project component template is the possibility to add various relations to other project component templates. Such relations can be used to model various dependencies of artifacts as required by SE process models like the OpenUP [EcFo15]. On one hand, this enables a hierarchy of project component templates with the properties subCompTemplSet and superCompTemplSet. On the other, content-related connections can be established using the relatedCompTemplSet. Finally, the property reqCompTemplSet allows one project component template to require the presence of others.

**Dynamic Processes**

The concepts for defining dynamic events and reactions to them are discussed in this section. The most important concepts are, in this context, the extension point and the extension (cf. Chapter 7). For both of these, we present the template concepts in Definition B.5.

**Definition B.5 (Extension Point Template)**

An extension point template models templates for extension points to the work unit in a project. It is represented as a tuple

\[
\text{extensionPointTempl} = (\text{type}, \text{name}, \text{extensionType}, \text{extensionSubType}, \text{abstractionLevel}, \text{parallelInsertion})
\]

where

- \( \text{extensionType} \in \text{ExtensionTempls} \) marks the type of extension template applicable to.extensionPointTempl.
- \( \text{extensionSubType} \in \text{STRING} \) marks the sub-type of extension template applicable to.extensionPointTempl.
- \( \text{abstractionLevel} \in \text{STRING} \) is the level of abstraction of extension templates applicable to this point.
- \( \text{parallelInsertion} \in \text{BOOLEAN} \) marks whether the extension template shall be inserted in parallel to the work unit template the former is attached to or sequentially after it.

ExtensionPointTempls describes the set of all definable extension point templates.

The extension point template features content- and process-related information: the type of extension can be specified using the two properties (extensionType, extensionSubType). Further, there is property abstractionLevel, which defines the abstraction level of the workflow in the entire process (e.g., operational development workflow vs. a workflow representing a phase of the process) to distinguish which extensions can be feasible. The extension point template corresponds to a marking of a change to a potentially running workflow instance. As discussed in Chapter 7 we apply a simple insertion into the workflow instance (i.e., Pattern AP1 from [WRR08]). For this pattern, three options for insertion exist: serial insert, parallel insert and conditional insert. The third option is redundant, as the added activity would be contemporarily inserted into the workflow instance matching the properties of the
situation. In such a case, no further condition is necessary. To distinguish between option one and two, the property \textit{parallelInstertion} is applied.

To classify the extensions made to the process, we further introduce the concept of the \textit{extension template} in (cf. Definition B.6).

\textbf{Definition B.6 (Extension Template)}
An \textit{extension template} models templates for extensions to process enactment. It is represented as a tuple \( \text{extensionTempl} = (\text{type}, \text{name}, \text{assignmentTempl}, \text{extensionPointTemplSet}, \text{extensionSubType}, \text{abstractionLevel}, \text{skillLevelSet}) \) where

- \( \text{assignmentTempl} \in \text{AssignTempls} \) defines the concrete human assignment that marks the content of the extension based on \( \text{extensionTempl} \).
- \( \text{extensionPointTemplSet} \) is the set of extension point templates, to which \( \text{extensionTempl} \) is applicable with \( \text{extensionPointTempl} \in \text{ExtensionPointTempls} \).
- \( \text{extensionSubType} \in \text{STRING} \) marks the sub-type of extension applicable to \( \text{extensionPointTempl} \).
- \( \text{abstractionLevel} \in \text{STRING} \) is the level of abstraction for which \( \text{extensionTempl} \) is applicable.
- \( \text{skillLevelSet} \) is a finite set of skill levels, one of which a human executing the extension shall possess with \( \text{skillLevel} \in \text{SkillLevels} \).

The extension template corresponds to an abstract concept that generalizes more concrete sub-concepts. Therefore, \( \text{ExtensionTempls} \) is defined as follows:

\[ \text{ExtensionTempls} := \text{FollwowActTempls} \cap \text{MeasureTempls} \cap \text{ExcHandTempls}. \]

\( \text{FollwowActTempls} \) is the set of all definable Follow-up Activity Templates (used for activity coordination and detailed in Chapter 10), \( \text{MeasureTempls} \) is the set of all definable Quality Measure Templates (used for software quality management and detailed in Chapter 9), and \( \text{ExcHandTempls} \) is the set of all definable Exception Handling Templates (used for exception handling and detailed in Chapter 11). These three are disjoint subsets of \( \text{ExtensionTempls} \).

The extension template features, same as the extension point template, a sub-type (\text{extensionSubType}) and abstraction level (\text{abstractionLevel}). Furthermore, it features a set of extension point templates for which it is applicable (\text{extensionPointTemplSet}) and a relation to an assignment template (\text{assignmentTempl}) that captures the human activity to be used to extend the process. In addition, it can also be specified, what skill level the human executing the extension should have (\text{skillLevelSet}). For more information on these properties and a detailed discussion of their application for integrating software quality measures into the process, we refer to Chapter 9.

The extension of a process can become necessary in many cases. We have discussed different cases for that in Chapter 4: task coordination (requirement \text{R:Coord}), process exception handling (requirement \text{R:Exc}), and software quality management (requirement \text{R:Qual}). In alignment with these cases and requirements, we have introduced three concrete sub-types of the abstract extension concept. These have been discussed in detail in the Chapters 9, 10, and 11.

\textbf{B.2. Consistency Checks}

This section discusses the consistency checks and conditions we created for the CPM concepts. It is split up regarding the different areas the CPM framework covers. These checks are extensible and do not claim to be complete. They are a starting point influenced partly by sources from literature and experiences from practical settings.

\textbf{B.2.1. Basic Concepts}

This section discusses consistency checks for the basic concepts applied for extending workflows.
Template and Individual Concepts

This check deals with the relation of template and individual concepts. Both concept sets share similar properties and the former set is used to pre-define the relations between concepts of the latter one. Therefore, individual concepts must not ignore these definitions. Figure B-4 illustrates a concrete case prohibited with this check. In this case, atomic task template ‘Coding’ is connected to the tool template ‘IDE’. However, a concrete individual has a connection to the static code analysis tool PMD instead.

![Figure B-4: Consistency check: template properties](image)

Work Unit Containers

For the work unit containers we apply consistency checks for various problems. Figure B-5 illustrates cases where properties of work unit containers have been set erroneously. Case a) deals with a work unit container without any work unit. In turn, case b) shows a work unit container requiring another one not contained in the same project. Such a container is out of control of the current project and hence does not contribute any results to it. Cases c) and d) concern work units that read or write project components not read or written by its container. The CPM framework’s definition implies that such components are exchanged with the container and distributed to its work units. Therefore, cases c) and d) should be prevented. In case e), a work unit container is defined to have no workflow instance but still has a connection to one. This collides with the definition of the ‘noWorkflow’ property and the workflow instance is redundant.

![Figure B-5: Consistency check: work unit containers](image)
Work Units

The definition of work units might contain certain erroneously set properties. Figure B-6 illustrates an undesired case for it. It concerns the usage of the work unit: It should be connected to a human-centric activity (assignment activity) or to a sub work unit container or work unit. If none of them is applied, the work unit will terminate right after its activation and would thus be useless.

![Figure B-6: Consistency check: work units](image)

Dependencies

The dependencies between work units and containers may imply erroneously specified properties interfering with correct execution. Figure B-7 illustrates three undesired cases. Cases a) and b) show different examples of circular dependencies with work unit dependencies (a) and work unit container dependencies. Such cases might produce deadlocks and should thus be prevented. A special case for the work unit dependency is shown in case c): If such a dependency is set to a work unit that is omittable, the dependency will not be satisfied if the work unit is be omitted. Therefore, we also prevent the setting of such dependency.

![Figure B-7: Consistency check: dependencies](image)

Variables

The variables used for governing the execution trace of the workflow instances are modeled in the context management component. This includes our concept for abstraction of internal workflow logic (cf. Chapter 7). The involved concepts might also imply erroneously set properties interfering with correct execution. Figure B-8 illustrates various cases for that. The connection to the variables in the WfMS can only be established if all variables are correctly mapped. Therefore, incorrect naming (case a) or incomplete mapping (case b) should be prevented. As the CPM framework does not monitor the correctness of all read and write operations on the variables and we have want to enable a standard trace for each executed workflow instance, each work unit container template must supply initial values for all variable templates (violated in case c). Similarly, each modeled human decision must have at least one decision alternative, otherwise the human might not make the decision (violated in...
case d). For each of these decisions, a standard alternative may be defined to unburden the human from the decision. To prevent ambiguities, for each decision, there must be exactly one standard alternative (violated in case e). The decision alternatives are modeled as abstraction of the workflow variables. Therefore, each alternative must set at least one of the variables (violated in case f). Otherwise, the alternative will have no effect at all.

**Figure B-8: Consistency check: variables**

### B.2.2. Extrinsic Workflows

This section discusses modeling conditions and checks for the concepts realizing extrinsic workflows for SE issue processing.

#### Modeling Conditions

This section presents the modeling conditions enforcing properties on the building blocks that enable the creation of block-structured workflows.

**Condition C1:** Each workflow shall not have multiple start or end points. This promotes simple and understandable models as suggested in [MRv10]. Such a start or end point can by a single building block template or multiple building block templates that are connected in parallel.

**Condition C2:** Each activity shall have at least one connection to other activities. This condition ensures that workflows are buildable, as a workflow cannot be built from unconnected activities since it cannot be determined when to execute this activity. The exception from this condition are containers with only one contained activity. The latter shall have no connection to other activities as they are outside the container.

**Condition C3:** No cyclic sequencing shall be specified, as this is error-prone: It might be impossible to determine start and end point of a cyclic workflow. Furthermore, if a cycle were integrated in a workflow, there will be no clear exit condition for that cycle making execution nondeterministic. If activities are to be executed more than once, this shall be specified using the *loop template*.

**Condition C4:** The activity structure shall be simple. An activity shall have only one successor and one predecessor. If multiple successors are needed, one can be defined as successor and the other shall be specified as parallel to that successor. This limitation is introduced to support simplicity and understandability of the models. Furthermore, the specification of multiple successors of an activity without specifying how they should be executed (in parallel? conditional?) results in nondeterministic models. However, complex workflow modeling is enabled in a defined way using the specialized building block templates.

**Condition C5:** A building block template shall not be sequentially connected to another building block template to which it is also connected in parallel. Such a connection is inconsistent, specifying that it should be executed after (before) and parallel to the other building block template at the same time.
Condition C6: The different specialized building block template concepts (sequence template, parallel template, loop template, and conditional template) enable hierarchical specification of declarative workflows. The constraints utilized to structure the building block templates (hasSuccessor and hasParallel) shall be defined in a way that does not violate this hierarchical specification as this would make the structure more complicated and may even introduce inconsistencies. This implies that a building block template is not contained in two different other building block templates and that it has no connections to other building block templates that are not contained in the same building block template. Figure B-9 shows inconsistently specified examples. The inconsistent loop template shows a constraint (between activity 3 and 4) that violates hierarchical specification. Generation of a block-structured workflow is not possible, as the system would generate LOOP nodes around the activities 2 and 3, and activity 3 would have a connection with activity 4 that violates the block structure.

![Inconsistent concept examples](image)

**Figure B-9: Inconsistent concept examples**

Condition C7: A loop template shall only contain one building block template. This can be a simple activity or any other building block template, enabling the looping of any structures. This constraint prohibits inconsistent specification as shown with the inconsistent loop template in Figure B-9. That specification lacks a connection between activity 2 and 3. Simple modeling is again supported by defining that the loop template is for repetitive execution of a contained activity or a structure that is represented by another building block template.

Condition C8: A parallel template shall contain at least two building blocks. This condition is introduced to support simple and readable process models. A parallel template with only one contained building block template does not endanger workflow correctness. However, it would add unnecessary AND splits and joins to the workflow.

Condition C9: A parallel template shall contain only building blocks that are connected in parallel. This constraint again supports simple hierarchical modeling, prohibiting confusing and error-prone structures as shown by the inconsistent parallel template shown in Figure B-9.

Condition C10: A sequence template shall contain at least two building blocks. This condition avoids specification of unnecessary building block templates, since a sequence template containing only one activity is similar to only specifying that contained activity without the sequence template.

Condition C11: A sequence template shall contain only sequentially connected building blocks. As with Condition C9, this condition supports a clear definition of the building block templates. A structure as shown by the inconsistent sequence template in Figure B-9 is thus prohibited as it also contains the parallel activities 3 and 4. On the other hand, it also has no specified connection between the parallel activities 3 and 4 and the sequential activities 5 and 6.

Condition C12: A sequence template shall contain a clear start and end point. This condition avoids cyclic dependencies of the activities in the sequence template.

Condition C13: A conditional template shall only contain unconnected activities or building block templates. This condition is applied because there will be only one or none of the contained building block templates selected for execution, and connections between them would thus produce inconsistencies.

Condition C14: A conditional template shall contain a minimal number of activities / building block templates. If the conditional template is defined as optional, it must contain at least one activity, else it would only add complexity to a workflow generating XOR splits and joins with no contained activities as shown in Figure B-9. If the conditional template is not defined as optional, it must contain
at least two activities since it would otherwise produce an inconsistent XOR pattern in the workflow containing only one branch.

Besides the sequencing constraints that are always only checked locally for the container or current building block template, there are also the existence constraints. These are in place for checking the soundness of a subset of activities that has been chosen due to contextual properties and are checked recursively for one container. However, to prevent modeling of containers that are inconsistent or foster inconsistent activity subsets, two conditions regarding the existence constraints are added to the build time checks:

**Condition C15:** One activity shall not both require and mutually exclude the same activity.

**Condition C16:** If an activity requires another activity, the latter must also be part of that container. If this is not the case, every activity subset containing the first activity will necessarily be inconsistent. An additional constraint for the mutual exclusion constraint is not needed, as it is possible to integrate two mutually exclusive activities in the candidate set of one container. All activity subsets not containing both of them will then be consistent.

In the following, we describe a mapping of these conditions to concrete checks applied on the different concepts. These checks have been implemented as exemplarily shown in Chapter 13 for the *sequence template*.

The conditions for the *sequence template* realize the following subset of the aforementioned modeling conditions (cf. Figure B-10): hierarchically separated modeling (cf. C6) is checked (cf. case c). The other checks deal with the conditions that directly apply to the *sequence template*: The correct number of contained building block templates (cf. C10) is enforced (cf. case b) and the correct connections between these (cf. C11) is governed (cf. case a). Finally, the presence of a single start and end point within the *sequence template* (cf. case d and e) is enforced (cf. C12).

**Figure B-10: Consistency check: sequence template**

Similar checks are applied for the *parallel template* (cf. Figure B-11). Again, hierarchically separated modeling (cf. C6) is enforced (cf. case c). In addition, the correct connections between contained building block templates (cf. C9), and their correct number (cf. C8) is also checked (cf. case a and b).
The checks applied to the loop template also implement C6, enforcing hierarchically separated modeling (cf. Figure B-12 case b). In addition the correct number of contained building block templates (cf. C7) is also checked (cf. case a).

Concerning the declarative container template, the presence of a single start or end point (cf. C1) is checked (cf. Figure B-14 case a and b). As defined in C1, both start and end point may contain multiple building block templates if they are connected in parallel. The presence of an unconnected building block template within a declarative work unit container is prohibited as well. This will only be permitted if the container contains exactly one building block template. In that case, the building block template will have to be unconnected (cf. C2 and Figure B-14 case c). Another check prohibits cyclic dependencies between contained building block templates (cf. C3 and case d). Furthermore, a consistent container must only contain consistent building block templates (cf. case e). Two other checks deal with the existence constraint. It is ensured that no building block template in a container requires and excludes the same activity (cf. C15 and case f). Finally, no building block template in a container shall require another building block template that is not part of the container or one of its contained building block templates (cf. C16 and case g).
B.2.3. Quality Management

This section discusses the realization of the agent structure utilized in Chapter 9 for automatic software quality measure prioritizing. The agent structure must be capable of both realizing the bidding process for the proactive measures and the voting process for the reactive measures. The bidding process shall favor agents whose goals are not in a good state. If this is the case, an agent takes place in the bidding process. If this applies for none of them, all can take place. If an agent wins one round, it may place one of his proactive measures in the list from which, at a later time point, measures for application will be selected. The voting process is different. Here, different agents vote on all measures in the reactive measure list that are attributed to their goal. That way, measures supporting multiple goals will have a higher probability to come to execution.

To be able to realize these two prioritizing processes, the agent structure is defined as depicted in Figure B-15. The AGQM agent is responsible for managing the multi-agent system component. It instantiates the other agents and determines whether a reactive or proactive measure will be proposed. For each defined goal, a goal agent is instantiated. In the proactive section, the goal agents communicate with the session agent to realize the bidding process. Thereby, the session agent takes the role of the “buyer” and thus selects the proactive measure from the goal agent with the highest bid. Each goal agent places bids according to its strategy. Initially, we have included three basic strategies. The strategies ‘offensive’, ‘balanced’ and ‘defensive’ influence the starting bid of the agents as well as win-or-lose adaptation based on the last bidding session. If insufficient points are left for the intended bid, the agent bids all points it has left. If an agent has no points left, it cannot place bids anymore until all agents have no points left, whereupon all points are reset to their initial value. Each agent has a list of proactive measures it could offer. Goals known to be at risk due to GKPI deviation are elevated to participation status in the bidding. If no report containing GKPI violations is received, all agents participate.
The reactive section is realized by the vote agent. Each time a report is received, the vote agent creates a weighted list of reactive measures using the report. To elicit the weight of each measure, the vote agent communicates with the goal agents. For each measure, a goal agent evaluates whether that measure is associated to its goal via the aforementioned connection of measures, metrics, KPIs, and goals. In each voting process, a goal agent distributes all of its points (initially allocated at the beginning of the iteration) uniformly to all measures in the current report that are associated to its goal. If multiple agents vote on one measure, the points are aggregated. If no report has been received yet, the voting process cannot be conducted. In that case, a proactive session is substituted. That way, the multi-agent system component creates a new ordered list of measures that mirror the predefined importance of the project’s quality goals.

B.3. Algorithms

This Chapter includes a set of additional algorithms not discussed in the main chapter of this work.

B.3.1. Basic Workflow Enactment

This section deals with algorithms needed for contextually extended workflow enactment as discussed in Chapter 7.

Activity Marking

This section shows algorithms for marking omittable and repeatable activities.

Omittable Activities. Activities in a workflow can be omitted due to the XOR pattern. In that case, there are points in the execution when it is clear that the execution of the respective activity will not happen in this instance of the workflow. These points correspond to the execution of other activities called terminator activities as described in Chapter 7. Algorithm B-1 is used to mark omittable activities and establish connections between an omittable activity and its terminator activity.

Algorithm B-1: markOmittable (Pseudo Code for marking omittable activities)

| Require: Decomposed Workflow list P {Blocks, Activities}, List targetBranch, List activitiesToConnect |
| 1: for all elements in targetBranch do |
| 2: if not activitiesToConnect.empty() |
| 3: connectNodes(element, activitiesToConnect, 'omittable') |
| 4: end if |
| 5: if element ∈ blocks |
The algorithm is explained in the following and graphically illustrated in Example B-1. The algorithm takes the decomposed workflow list discussed in Chapter 7 as input as well as a decomposed workflow list representing the point in the workflow where this execution of the algorithm should operate on. For the initial execution on a workflow, this will be the whole workflow. It also expects a list of activities, whose execution triggers the deactivation of a particular activity that is empty at the beginning (called terminator activities). The algorithm iterates through the workflow list and mass terminator activities \( \text{activitiesToConnect} \) it marks the current activities as omittable and connects it bidirectionally with its terminator activities (Line 3) (cf. connectNodes() and the activities 1-5 in the example). This is needed for each activity when a workflow is executed later on. However, the algorithm also adds the markings to the blocks. These markings will be used to facilitate the making of activities that are inserted into the workflow when it is already running (cf. Algorithm B-2). If the algorithm encounters a block, a new list is created (Line 5 and 6). This new list is used for new terminator activities of the encountered block and other blocks within it. This is done since the lists are passed as call-by-reference so that each level of the recursion has its own list that can also be used for further levels of the recursion but does not change the lists of upper levels of the recursion. That way, in Line 6 only the values in the list are copied (cf. e.g. in recursion Rec1 in the example). This is done because activities can be deactivated by multiple other activities. Consider e.g., multiple nested XOR patterns: An activity within an inner XOR pattern can be deactivated by activities of other branches of each of that XOR patterns. If a XOR block is encountered, the next step is the determination of the terminator activities for the current branch of that XOR pattern (Line 10 and 11) (cf. the initial call and the Rec2 recursion in the example). This is done by the algorithm getTerminatorActivities already described in Chapter 7. The algorithm is then called recursively for the current branch with the current childConnectActivities list and the new terminator activities for the current branch (Line 12). The same happens if another pattern as XOR is encountered (Line 16-20) (in that case without new terminator activities).

Example B-1 (markOmittable Steps):
For this example, the workflow used for Example 7-15 in Chapter 7 has been slightly adapted to contain two nested XORs to better demonstrate the XOR handling. Therefore, Figure B-16 and Figure B-17 show the adapted workflow and the concrete steps executed, both indicating the different recursion levels.
Since no activities follow the XOR1 pattern, the termination of the whole workflow is taken as terminator activity for all comprised activities. For activity 4, also the succeeding activity 5 is added.

**Repeateable Activities.** Due to the LOOP pattern, activities specified in a process model can be repeatable and can occur more than once in its execution. Therefore, they have to be marked so that the context management component is aware of this fact and can create new instances of the relating concepts when an activity is repeated. When activities are repeatable it may also be of interest to know when another execution of these can no more happen for a given workflow instance. This is a somehow similar case to the omittable activities and the XOR pattern: At certain points in the execution, it is clear that the respective looped activity will not be executed another time. This point is
the execution of the first activity after the LOOP. In the case of multiple nested LOOP patterns this applies to the outer LOOP pattern. Due to the similarity to the markOmittable Algorithm we refrain from separately discussing the markRepeatable algorithm.

Adaptation Markings. As discussed in Chapter 7, newly inserted activities are analyzed and marked by a separate algorithm instead of re-running all initial marking algorithms. This involves different cases. First, there are different markings: the ‘repeatable’ marking, the ‘omittable’ marking, the list of activities an activity terminates, and the list of activities that are terminated by the activity. The first three markings apply for all activities of one branch while the last one, indicating an activity as a terminator activity, only applies for the first activity in a branch or the first activity in a branch after a XOR or LOOP pattern. Different situations require that the algorithm adopts the marking in different ways. These situations are explained in the following and illustrated in Figure B-18, starting with the generic case and showing the more specific cases afterwards (where this is a refinement, i.e., the generic cases also apply to the more specific cases):

1. **Inserted into a list, not as first element** (i.e., the list represents the workflow instance or a branch of a pattern): In this case, only the markings (repeatable, omittable, and the connection to the terminator activities) have to be adopted from any other activity in the branch. It is assumed that in this case, the list in which the activity has been inserted cannot have been empty before because it can only be the entire workflow instance, a branch of an AND pattern, or a LOOP pattern. None of these would make sense without any contained activities.

2. **Inserted as first element into a list** (representing the workflow instance or a branch of a pattern): Being the first element in the list, the insert activity can be the terminator activity for other activities. As it is assumed (as in case 1) that the list was not empty before, the connections to activities that are terminated by the current activity can be acquired from the former first activity in the list, which is now the second activity. This activity might also be a pattern containing multiple activities. However, for this algorithm this does not matter as the marking that have been previously applied to the workflow lists treat patterns (blocks) from the outside like simple activities and apply the same markings to them.

3. **Inserted into a list after a LOOP pattern in the same branch** (i.e., the list represents the workflow instance or a branch of a pattern): The activities in the LOOP pattern are repeatable and need terminator activities to indicate that they will not be repeated again. Therefore, the LOOP and all containing activities have to get the inserted activity be added as a terminator activity. Taking a naive approach, one might assume simply taking the markings from the successor of the inserted activity suffices. However, it is possible that it is not a successor in the workflow instance.

4. **Inserted into a list after a XOR pattern in the same branch** (i.e., the list represents the workflow instance or a branch of a pattern): In principle, this is the same case as the previous one. However, XOR patterns have one special property: If they have an empty branch it is possible that no activity of the XOR pattern comes to execution. This, in turn, implies that the newly inserted activity must also be added to the activities of a XOR or LOOP pattern directly before the XOR pattern that is the predecessor of the inserted activity.

5. **Inserted into a list that represents the empty branch of a XOR pattern**: In this case, no activity is in place in the list to adopt the markings from. Therefore, the markings can be adopted from an activity in another branch and mutual terminator activity markings have to be established between the branches.
In the following, Algorithm B-2 is presented that applies the markings for a newly inserted activity:

**Algorithm B-2: markInsertedActivity** (Pseudo Code for marking newly inserted activities)

```pseudo
Require: List targetBranch, Activity target, Block surroundingPattern
1: if not targetBranch.size == 1
2:   Element element ← targetBranch.getPreviousElement(target)
3:   if element == NULL
4:     element ← targetBranch.getNextEelement(target)
6:   end if
7:   adoptMarkings(target, element)
8: end if
9: if targetBranch.firstElement == target
10:   if not targetBranch.size == 1
11:     connectTerminatorActivity(target,targetBranch.getNextElement(target))
12: end if
```
Algorithm B-2 takes as input a newly inserted activity, its branch, and the pattern surrounding that branch. First, the algorithm deals with case 1, which is the simplest case: In Line 1-8 it inherits the markings (repeatable, omittable, and potential terminator activities) from another activity in the same branch. This is only done if the new activity is not the only one in the branch, which might be the case if the surrounding pattern is a XOR pattern. Case 2 is dealt with in Lines 9 - 12: if the new activity is the first in the target branch, the list of activities it terminates is taken from the former first activity in the branch that is now the second one. The next case processed involves insertion within the empty branch of a XOR pattern (case 5). In this case, all markings are adopted from the first activity of another branch (Lines 13-20). This is done to establish connections to the other activities that are outside of the XOR pattern because the first activity of each branch of a XOR pattern has equivalent relations to activities that are outside of the XOR pattern. The mutual marking of the activities of the different branches in the XOR pattern are then applied in Lines 21-26: First, the first activity of each branch is added to the terminator activities of the newly inserted one. The latter is then added to the terminator activities of all activities in the other branches in the XOR. The final part of the algorithm (Lines 30-44) deals with cases 3 and 4. It takes the predecessor of the inserted activity and, if it is a LOOP or XOR, it adds the new activity to its terminator activities. In case of an XOR, this action is repeated. The function used to add the terminator activity (in this case `addAsTerminatorActivity()`) also applies the marking recursively to all activities contained in the LOOP / XOR.

**Computational Complexity of the Algorithms**

To conclude this section regarding algorithms, we will elaborate briefly on their computational complexity. For most of them, however, this is not a critical issue as they are applied during build time. Furthermore, their complexity depends on the elements in the modeled workflows and the
number of these elements is recommended to be kept rather small for various reasons. For example, [MRv10] recommends to keep the number of nodes in a workflow below 50. Our practical experiences show that it is very uncommon that a huge number of workflows or workflows with a huge number of elements are created in a modeling session. Also, only one of the algorithms (markInsertedActivity) is to be executed during runtime and this might impact operational performance. Therefore, we have put emphasis on a low complexity for this algorithm. In Table B-2 the complexity of the different algorithms is shown.

<table>
<thead>
<tr>
<th>Algorithm</th>
<th>Complexity</th>
</tr>
</thead>
<tbody>
<tr>
<td>decomposeWorkflow</td>
<td>$O(#\text{nodes in workflow})$</td>
</tr>
<tr>
<td>markOmittable</td>
<td>$O(#\text{elements in list} \times #\text{XORs.branches})$</td>
</tr>
<tr>
<td>markRepeatable</td>
<td>$O(#\text{elements in list} \times #\text{LOOPS})$</td>
</tr>
<tr>
<td>getTerminatorActivities</td>
<td>$O(#\text{elements in list} \times #\text{element.branches})$</td>
</tr>
<tr>
<td>markInsertedActivity</td>
<td>$O(#\text{surroundingPattern.branches} \times #\text{branch.activities} + #\text{preceding LOOPS or XORs})$</td>
</tr>
</tbody>
</table>

The algorithm ‘decomposeWorkflow’ directly depends on the number of nodes in the analyzed workflow. The other three build time algorithms depend on the number of elements in the output list of the first workflow, as well as on the number of branches of the workflow patterns. However, as the build time algorithms are executed in a row or respectively call each other, an overall computational complexity for analyzing one modeled workflow can be expressed as follows:

$$O(\#\text{nodes} + (\#\text{elements in list} \times \#\text{XORs.branches}) \times (\#\text{elements in list} \times \#\text{element.branches}) + (\#\text{elements in list} \times \#\text{XORs.branches}) \times (\#\text{elements in list} \times \#\text{element.branches}))
= O(\#\text{nodes} + (\#\text{elements in list})^2 \times \#\text{XORs.branches} \times \#\text{element.branches} + (\#\text{elements in list})^2 \times \#\text{LOOPS} \times \#\text{element.branches})
= O(\#\text{nodes} + \#\text{XORs.branches} + \#\text{LOOP}) \times (\#\text{elements in list})^2 \times \#\text{element.branches})$$

Having the properties of the workflows just discussed in mind, this complexity seems quite adequate and should not hamper modeling. Nevertheless, we have managed to realize ‘markInsertedActivity’ with a much smaller complexity, as it is to be executed during runtime for every activity inserted into a potentially running workflow instance. For brevity, we omit a separate discussion of the algorithms for extrinsic workflow generation as they operate on similar structures. Furthermore, extrinsic workflows are mostly smaller than intrinsic ones as they are enacted.

### B.3.2. Extrinsic Workflow Generation

This section presents algorithms related to the generation of workflows from the declarative specification we have introduced in Chapter 8.

The algorithm $BBtreatment()$ is utilized to convert building blocks into parts of an executable workflow. The conversion is abstracted (from the creation of context and process management concepts) using simple functions as, e.g., $insertNode()$ for the insertion of one activity into a workflow.

#### Algorithm B-3: BBtreatment

(Pseudo Code for inserting building blocks into workflow)

```plaintext
Require: Building Block BB, Work Unit Container skeleton, Arc marker
Return: String errorCode
1: String errorCode ← empty String
2: if $BB \in \text{Activities}$
3: insertNode(BB, skeleton, marker)
4: else if $BB \in \text{Sequences}$
5: errorCode ← sequenceTreatment(BB, skeleton, marker)
```
The algorithm expects a building block as well as the workflow skeleton to be extended including a position marker as input. If that building block is a simple activity, it is inserted into the workflow. If it is of another type, the insertion is handled by specialized algorithms. One of these, \texttt{parallelTreatment()} is exemplarily discussed in Algorithm B-4.

\begin{algorithm}
\caption{parallelTreatment}
\caption{(Pseudo Code for inserting a parallel into a workflow)}
\begin{algorithmic}[1]
\Require Building Block BB, Work Unit Container skeleton, Arc marker 
\Ensure String errorCode
\Function {emptyString}{}
\State errorCode := empty String 
\EndFunction
\Function {parallelTreatment}(	exttt{BB}, skeleton, marker)
\If {BB.parallelBBset is empty}
\State return "emptyParallel"
\ElseIf {BB.parallelBBset.size < 2}
\State errorCode := BBtreatment(parBB, skeleton, marker)
\Else
\State AndSplit split := insertParSplit(marker, skeleton) 
\State List branches := new List() 
\ForAll {BB.parallelBBset}
\State insertBranch(split, marker) 
\State errorCode := BBtreatment(parBB, skeleton, marker)
\State branches.add(marker)
\EndFor
\State insertParJoin(marker, split, skeleton, branches)
\EndIf
\EndFunction
\end{algorithmic}
\end{algorithm}

\texttt{parallelTreatment} inserts no pattern if no building block is contained in the parallel. If it contains only one building block, no pattern is needed either but only the building block is inserted. If multiple building blocks are contained, each is added in a separate branch of an AND pattern.

For brevity, we will refrain from discussing the computational complexity also for the extrinsic workflow generation. As stated in Chapter 8, the modeled workflows can contain many activities. However, for the workflow generation algorithms, the number of activities that are really in place for a specific situation is important. Usually, this is a rather small subset of the modeled activities.
C. Basic Actions for Process Enactment

This appendix discusses concrete actions to be performed in order to enact processes with the CPM framework.

Create Project

When a project and its process realized by a structure of workflows have been created with the template concepts, that structure can be used for concrete project executions. Therefore, a concrete project including its process must be created in the CPM framework. The action for this is shown in the following. Note that we assume that a project only has one defined process. This is an abstraction that may not hold for all projects, however, multiple processes for one project can be added with low effort within the CPM framework.

This action is applied to create a new project with its associated work unit container.

Preconditions: -
Input: project template ∧ roles, project components, and tools required by the assigned work unit container template.

Actions:
- Create project concept.
- Create contained areas as defined in template
- Apply: Create Work Unit Container

Output: project with work unit container in state ‘Created’.

The ‘Create Project’ action implies the creation of its associated process that is captured by one basic work unit container (and its potential sub work unit containers). The latter is created by the following action ‘Create work unit container.

Create Work Unit Container

This action is applied to create a new work unit container from a work unit container template. As opposed to WfMS where workflow instances are directly started from their templates, the containers in the CPM framework are created without starting them (or the relating WfMS workflow instances). Thus, a workflow structure for the complete process of a project can be created without having to start each of the future workflow instances.

Preconditions: -
Input: work unit container template ∧ values for roles, project components, and tools

Actions:
- Create work units as defined in template and assign to work unit container.
- Create assignment as defined in template and assign to work unit container.
- Create assignment activities as defined in template and assign to assignment.
- Create atomic tasks as defined in template and assign to assignment activities.
- Assign concrete tools to atomic tasks as defined in template.
- Set process variables as defined in the template.
- Assign concrete humans for the container roles.
- Assign concrete inputs/outputs for container (including structure of project components as defined in super/subCompsSet properties).
C Basic Actions for Process Enactment

- Assign main human with main role also to the assignment. Distribute the humans filling the roles of the container to the work units. Add responsible party of each work unit to the relating assignment activity.
- For all defined dependencies defined by the template for work units, apply the action ‘Create work unit container’ to create the containers (and work units) that are the targets of the dependencies and then connect them via the ‘Add work unit to work unit dependency’ and ‘Add work unit to container dependency’ actions.

Output: work unit container in state ‘Created’.

After a concrete work unit container has been created, it remains in the state created and also does not automatically initiate the start of its relating workflow instance. This has the advantage that for a project, its whole process can be prepared with a workflow structure without having to start one or more of the involved work unit containers or workflow instances. When all concepts and information is in place, a work unit container can be explicitly started including the creation / start of its relating workflow instance. To start a project, its top-level container thus has to be started. The action to execute such a start is shown in the following.

Start Work Unit Container

This action is applied to start a work unit container.

Preconditions: work unit container must be in status ‘Created’.

Input: work unit container

Actions:
- Instantiate a new workflow instance from a workflow template that is connected to the template of the current work unit container.
- Connect the workflow instance and the work unit container.
- Set work unit container status to ‘Started’.

Output: work unit container in state ‘Started’.

When a container and its associated workflow instance is running, its progress is governed by the work units that are the mappings of the activities in the workflow instance. With these, connections to sub containers or human tasks (assignment activities) are managed as discussed in Chapter 7. Thus a sound management of their states and especially their termination is crucial as the workflow instance can only continue when one or more active work units terminate. Therefore, the action for checking if a work unit may terminate is explicitly defined in the following.

Check Work Unit Termination

This action is applied to check if a work unit can terminate.

Preconditions: work unit must be in state ‘Started’.

Input: work unit

Actions:
- Check if associated assignment activity is finished.
- Check if required guidance has been used, i.e. guidance in ‘guidanceSet’ (of related assignment activities or project components or, if it is the final work unit of the assignment, also the assignment) are satisfied.
- Check dependencies of work unit are satisfied, i.e. if they are ‘finalized’ (or, in case of a work unit dependency with ‘oneShot’ behavior ‘executed’).

Output: work unit in state ‘Started’ or ‘Finished’.

As discussed in this chapter, the CPM concept applies multiple instances of the concepts relating to a looped activity in the WfMS. That means, if a WfMS activity is executed repeatedly due to a loop, the relating work unit and related concepts are already finished. So a new work unit instance has to be created, supplied with the values for markings and human activities from the prior work unit instance,
and has to be linked with the latter as well as with other containers and work units the prior work unit instance had dependency connections to. This is managed explicitly by the following action.

**Create new Work Unit Instance**

This action is applied to create a new instance of a work unit if the relating workflow activity is executed multiple times in a loop.

*Preconditions*: work unit must be in state ‘Finished’ and relating WfMS activity comes to execution again.

*Input*: work unit

*Actions*:

- Create new work unit and relating activity concepts and adopt values from the prior work unit.
- If the work unit is defined for single execution by the `singleExec` property only create the work unit without any other concepts and start it. That way, the new instance will terminate immediately like a ‘blind activity’ that will have no effect on the container and be invisible to the human.
- Check if work unit has a dependency. If yes, create the same dependencies for the new work unit. If the target container (or the container containing the target work unit) has a planned successor iteration (via the `futureExec` property), take that container as the target and link it with the new work unit. If there is no future iteration, create a new container with the values in place and link it with the new work unit.
- Check for a dependency who had the prior work unit instance as a target. If there are one or more of these having the `lastShot` behavior, link the dependency to the new work unit instance.
- Start the work unit.

*Output*: new work unit in state ‘Started’.

As discussed many times in this work, SE process enactment is rather dynamic and thus changes to the workflow structure of a project might often be necessary. For example, a new workflow instance / work unit container may have to be added due to a changed or new customer requirement that needs to be realized. Such a new container has to be integrated into the workflow structure by adding new dependencies between that new container and a container that is part of the workflow structure. Therefore, in the following, concrete actions for adding such dependencies are shown starting with the dependency of a work unit to another container.

**Add Work Unit to Container Dependency**

This action is applied to create a new dependency between a source work unit and a target work unit container.

*Preconditions*: Source work unit and target work unit container must be in state ‘Created’ or ‘Started’.

*Input*: source work unit A target work unit container

*Actions*:

- Create dependency.

*Output*: newly connected work unit and container as illustrated in Figure C-1.

---

**Figure C-1: Add work unit to container dependency**
The addition of a dependency from a work unit to another work unit in another container is also possible as shown in the following.

**Add Work Unit to Work Unit Dependency**

This action is applied to create a new dependency between a source work unit and a target work unit. 

**Preconditions**: source and target work units in state ‘Created’ or ‘Started’.

**Input**: source work unit ∧ target work unit ∧ definition of behavior of new dependency

**Actions**:
- Create dependency.

**Output**: newly connected work units as illustrated in Figure C-2.

![Figure C-2: Add work unit to work unit dependency](image)

Changes to the workflow structure of a project may not only imply adding new requirements and additional workflow instances. It is also possible that, for example, a requirement can be canceled because its realization turns out to be unfeasible or too expensive. In such a case one or more containers might have to be excluded from the workflow structure. This implies removing dependencies between containers and / or work units. The actions for this are shown in the following starting with the removing of a dependency to a container.

**Remove Container Dependency**

This action is applied to remove mutual dependencies between work units in a source work unit container and a target work unit container.

**Preconditions**: source and target in state ‘Created’ or ‘Started’.

**Input**: source work unit container ∧ target work unit container

**Actions**:
- For all dependencies of work units in the source container to work units in the target container where the source and target work units are in state ‘created’ or ‘running’, apply: Remove work unit dependency.

**Output**: -.

Same as for a container, a work unit can also have a dependency to another work unit that also might need to be removed. The relating action is shown in the following.

**Remove Work Unit Dependency**

This action is applied to remove a dependency between a source work unit and a target work unit or a container.

**Preconditions**: source and target in state ‘Created’ or ‘Started’.

**Input**: source work unit ∧ (target work unit container ∨ target work unit)

**Actions**:
- Delete dependency
- For the source work unit apply: Check Work Unit Termination.

**Output**: -.
Another frequent change we have perceived in the projects of our industry partners is the moving of an activity / requirement / workflow instance from one point in the process to another. This happens in iterative development, when an activity is to be executed within one iteration but cannot be finished therein. Iteration deadlines are mostly firm and thus the activity (and its workflow instance) is transferred to another iteration. To facilitate this, the following action shows the moving of dependencies.

**Move Work Unit Dependency**

This action is applied to move a dependency between an old source work unit and a target work unit or a container to a new source work unit.

**Preconditions:** old and new source and target in state ‘Created’ or ‘Started’.

**Input:** old source work unit ∧ new source work unit ∧ (target work unit container ∨ target work unit)

**Actions:**
- If target is a work unit apply for new source and target: **Add Work Unit to Work Unit Dependency**, else apply **Add Work Unit to Container Dependency**.
- If target is a work unit apply for old source and target: **Remove Work Unit Dependency**, else apply **Remove Container Dependency**.

**Output:** newly connected concepts as illustrated in Figure C-3 (upper half for container dependency and lower half for work unit dependency).

---

One thing that also happens frequently in projects is the situation that activities must be handed over from one human to another. The cause for this might be for example the unavailability of one human or that an activity has been assigned to a whole team and the team leader then passes it on to a concrete human best suitable for the activity. For such cases, we have applied two different actions for distributing human activities. The first one, shown in the following, deals with the distribution of one concrete assignment activity from one human to another.

**Distribute Activity**

This action is applied to change the executing human of an assignment activity.

**Preconditions:** assignment activity must be in status ‘Created’, ‘Active’, or ‘Inactive’.

**Input:** assignment activity ∧ human

**Actions:**
- Remove executing human.
- Set new human as executor.

**Output:** assignment activity with new executor.
Another specific case is the distribution of a more complex activity, an assignment, from one human to another. In this case, the assignment might already be started and all comprised assignment activities must still be transferred to the new executor as shown in the following.

**Distribute Assignment**

This action is applied to change the executing human of an assignment and all of his related assignment activities belonging to that assignment.

*Preconditions: assignment in state ‘Active’ or ‘Inactive’.*

*Input: assignment ∧ old executor ∧ new executor*

*Actions:*

- Remove executing human of assignment.
- Set new executor as executor of assignment.
- For all assignment activities having the old executor and that are in state ‘created’ or ‘running’ apply Distribute activity with the new executor.

*Output: assignment with new executor.*
